HARRY CAMPBELL,
Senior Physician.

West End Hospital for Nervous Diseases, 73, Welbeck-street, London, W., Jan. 29th, 1923.

DEEP X RAY THERAPY.

To the Editor of The Lancet.

Sir,—The communication to The Lancet of Jan. 20th on this subject by Drs. R. Morton and H. B. Lee is of particular interest to me in respect of the sequelæ which they mention. At the last meeting of the Section of Electro-therapeutics of the Royal Society of Medicine, I showed that the secretion of mucus by the alimentary canal is interfered with by very small doses of radiation, and that this first change is followed by a bacterial invasion of the tissues, and may account for the subsequent changes which are known to occur, such as necrosis and ulceration of the intestinal mucosa, a disappearance of the platelets from the circulation, and possibly also the destruction of red cells and the cachectic conditions which follow massive doses of radiation. Mucus mechanically protects the tissues from bacteria. Dr. Neave Kingsbury mentioned experiments which showed that a bacterial invasion of the blood-stream followed these intestinal changes, and Dr. W. Cramer spoke of the similarity of the effects of withholding vitamin A, in which similar intestinal changes were found to occur, and suggested the desirability of feeding patients before and after radiation with diets rich in vitamins, with the object of counteracting these deleterious effects of radiation.

My object in writing this letter is to ask whether there is any clinical evidence of these effects of radiation. At the meeting it was mentioned that diarrhœa occurs both in patients and radiologists after large exposures to the abdominal region, and the time of its occurrence (two to three days after exposure) corresponds with my experimental results. It would be of interest to know whether there is in these cases an unusual amount of mucus in the stools. Further, whether either an increase or decrease of mucous secretion has been observed from the nasal and respiratory passages following radiation of the head or thorax. Dr. Morton mentions infection conditions of the lungs and ulceration of the bladder and rectum. At what time after radiation do these infective conditions occur?

It is also of particular interest to know when the anæmia occurs, and its particular characters, and whether a thrombopœnia has been observed. If, as seems probable, many of the sequela of radiation can be referred in the first place to a change in the alimentary or respiratory mucosa, then every endeavour must be made to protect these very sensitive regions from radiation. Also to prepare them for radiation by purgatives, diet, and other favourable conditions, just in the same way as a patient is prepared for a severe surgical operation.

I am, Sir, yours faithfully,
J. C. Mottram,
Director of the Research Department,
Radium Institute.

THE TREATMENT OF EARLY PULMONARY TUBERCULOSIS IN THE YOUNG ADULT.

To the Editor of The Lancet.

Sir,—With most of what has been recently written in The Lancet by Dr. C. Lillingston and Dr. Clive Riviere the majority of those whose work lies in a sanatorium will probably agree, especially the remarks on the misuse and abuse of graduated exercise as a method of treatment. Such statements, however, as "the doctrine of graduated exercise has done more harm than any other remedy"—coming from such an authoritative source are likely to bring a valuable method of treatment into disrepute. While valuable in suitable cases properly applied, this method is capable of doing harm if given without skill and experience. But surely this is true of most remedies of therapeutic value, and we should take care that we do not, for this reason, allow a valuable method of treatment to fall into undeserved disrepute. Such was the history of tuberculin, lauded for years, abused by many, and now so discredited, that it is probably not used to such small extent as it might be valuable. The same danger now appears to menace artificial pneumothorax, when one sees it advocated in all cases who do not suffer from one of a small list of contra-indications. Dr. Riviere's letter suggests that the method of graduated exercise is usually applied to all and sundry, regardless of the stage of their disease, or the effect of exercise upon it. That surely is a great fallacy! Neither graduated exercise, nor artificial pneumothorax, nor tuberculin, nor rest, nor any other known method of treatment is suitable for all cases all the time, though all of them are of value for some patients for some of the time, while no method is of any value to any patient any of the time which is not controlled by careful observation of the patients' symptoms and physical signs.

And here I would like to stress the great care required in the early weeks when this method is started in afebrile active cases, both in the very small graduations in the exercise given, and also in the look-out for mild symptoms of toxæmia insufficient to cause fever. If these things are carefully watched, as well as the temperature and physical signs, there is little chance of the method being pushed at such times and in such cases as to be responsible for "needless spread of the disease."

That the method is capable of much good, who that has used it in suitable cases, intelligently, can doubt? Many of these patients, in the less advanced stages of the disease, as the months go by, gradually lose their cough, expectoration, and other symptoms; put on weight, become keen on their food, and fit to undertake fairly prolonged exercise, while each examination shows a decrease of their physical signs. It is not possible to believe that these cases are victims of increased activity, especially when one hears of them years later leading healthy lives. It is true that all cases do not result so happily, otherwise tuberculosis would be shorn of half its terrors, but many do. It is also true that to try and obtain such results in three months is to court disaster. *Festina lente* must still be the motto for sanatoria. There are others of the more chronic type of many years' duration. Many such a one for whom there is no hope of permanent arrest of the disease can be brought by this method to a stage of tolerance or health as to allow of a useful and happy life, instead of a useless and therefore miserable one, as I have good reason to know.

Is it not surely best in the present state of our knowledge not to disparage any method of treatment at our disposal, but rather to pick out the good from each, using it at the proper time for the proper cases to the best of our skill and knowledge?

I am, Sir, yours faithfully,
C. Brodribb.

Pendyffryn Hall, Penmaenmawr, Jan. 23rd, 1923.

To the Editor of The Lancet.

Sir,—I was pleased to see that Dr. C. Lillingston, in his excellent article on this subject in The Lancet of Jan. 13th, drew attention to the danger of the doctrine of graduated exercise, which seems to have become a sort of fetish amongst a number of the profession. During four years' experience as a patient, and 12 years as a sanatorium doctor, I have seen very great harm done as a result of this so-called remedy. As Dr. Lillingston mentions, it is most difficult to graduate exercise and almost impossible to graduate the resultant auto-inoculation. Only last year I had under my care four or five patients from one particular centre where this treatment is used, or should we say abused, very freely, to whom the treatment had done infinite harm. This is surely a scandal, and Dr. Lillingston is to be thanked for having called attention to the great danger of the doctrine of graduated exercise.

I am, Sir, yours faithfully,
Nice, Jan. 24th, 1923. Arthur Hawkins.

THE TREATMENT OF WHOOPING-COUGH.

To the Editor of THE LANCET.

SIR,—I have read Dr. T. Izod Bennett's article on whooping-cough and its treatment in your issue of Jan. 27th. The lines of treatment he recommends are quite inapplicable to the vast majority of cases in general practice as the necessary supervision of the lavish employment of dangerous drugs which he recommends is lacking. Again, the practitioner who is continually jamming needles into his child patients will soon lose them. These are points of *practical* importance that cannot be overlooked. As a matter of fact, I find that, if you can get your cases reasonably early, all the severe symptoms can be abolished well under a month, generally in from two to three weeks, by the following treatment :—

1. Vapocresolene burned at night or in the most severe cases all day.

2. Pure benzol by mouth, six minims to the half ounce for a child of 6 with diminishing doses for lesser ages down to one drachm for a child of 1 year.

If, as so often happens, the child loses its appetite, I find the syrupus ferri phosph. co. soon restores it. Bromide, 1 gr. for each year, may in the severe cases be advantageously added to the whooping-cough mixture. I feel this letter ought to be written because the young practitioner is apt to base his treatment on articles written by experts in the medical press, and the treatment given is far too full of pitfalls to pass unchallenged.—I am, Sir, yours faithfully,

R. LEONARD LEY, M.B., B.C. Cantab.

Great Yarmouth, Jan. 26th, 1923.

PERMANGANATE OF POTASH IN SMALL-POX.

To the Editor of THE LANCET.

SIR,—With reference to my letter in THE LANCET of Dec. 2nd, 1922, on this subject, I find that, through inadvertence, I stated that the observations on the use of permanganate in small-pox at Zanzibar had been made by Dr. de Sousa, the acting principal medical officer. I now understand that this work was carried out by Dr. B. Spearman, the senior medical officer of health. I would like to express my regret for the mistake, to which Dr. Spearman has kindly directed my attention.—I am, Sir, yours faithfully,

ANDREW BALFOUR.

Wellcome Bureau of Scientific Research, Endsleigh-gardens, London, N.W., Jan. 26th, 1923.

FOREIGN METALLIC SUBSTANCES IN FOODSTUFFS.

To the Editor of THE LANCET.

SIR,—At the moment when this subject is before medical officers it may be appropriate to draw attention to a point requiring elucidation.

I find it generally suggested that heavy de-tinning in canned foods is due to inherent qualities in the foods so reacting—namely, vegetable acids in vegetable and fruit products and extractives in the case of soups and meat extracts: no explanation is given for lobster and shell-fish. Heavy de-tinning as now found does not follow on these lines, but is most probable in those canned goods which have a sodium chloride content, either concentrated in the process of their manufacture or deliberately added as part of the process of canning. The factors common to lobster, herring, pork and beans, soups and meat extracts, asparagus, tomatoes, spinach, and peas when canned are sodium chloride and a more watery consistency in packing than that of, say, corned beef. Where a spot of solder is added, all the elements of strong galvanic action are present in the lead-tin couple and sodium chloride solution as electrolyte; a small spot of bare iron in a "sanitary" tin gives the same effect in the presence of salt, whatever the nature of the substance canned, and more especially where the contents are "sloppy," whether the tin be lacquered internally or not.

The crimping of a "sanitary" tin lid can hardly avoid the cracking of lacquer, and, indeed, the tin plate itself so as to expose bare iron. Hence the rust about the lid edge externally and corresponding electrolysis within, especially where a good electrolyte is supplied in the form of sodium chloride. The couple here is tin-iron. The paper or rubber gasket, where present, is often deemed unsatisfactory in certain "springers," when really the packing medium—salt—should bear its share of blame, for it is at the line of crimping and consequent exposure of bare iron that the galvanic process is active and pin-hole perforation occurs. The wooden shaving or the paper case about canned lobster prevents the blackening of the fish, but does nothing for public health purposes. It is a mere concession to æsthetics.

In de-tinning the manufacturers are up against the old problem of how to prevent the pitting of steel plates on a launch's stern when the propeller is of gun-metal and sea water forms the electrolyte. The importance of the electrolyte, and especially of sodium chloride solution as electrolyte, should not further escape notice in the text-books and in the lore of the subject.

I am, Sir, yours faithfully,

W. M. WILLOUGHBY,

Jan. 24th. Medical Officer of Health, Port of London.

A TECHNIQUE OF SPINAL ANALGESIA FOR LAPAROTOMY.

To the Editor of THE LANCET.

SIR,—In connexion with a paper under this title by Dr. S. A. Lane, which appeared in THE LANCET of Jan. 20th, readers may be glad to be referred to a paper on the same subject published in your columns by Mr. F. L. Provis on Jan. 26th 1918 (p. 152). The method there described is identical in essentials and similar in details to that used by Dr. Lane. Whether Mr. Provis was actually the first to introduce this combination of "twilight sleep" and spinal analgesia I am unaware, but he brought the matter to my notice in July, 1917, since which time I have used his method in about 800 cases. At the Prince of Wales's General Hospital it has been adopted as a routine method for most gynæcological and many other abdominal operations for some four or five years. The method will be found in both Hewitt's and Blomfield's standard works on anæsthetics, and is even described in full detail in a recent elementary handbook on the subject.

Dr. Lane has been fortunate in avoiding "stovaine headache." This troublesome complication is most erratic in its incidence, sometimes being absent in a long series of cases and then reappearing without apparent reason. Careful avoidance of all unnecessary movement of the patient (active or passive) is the best insurance against headache, and the impossibility of this in a casualty clearing station explains its prevalence there. Minor operations under stovaine are well known to be more frequently followed by headache than major ones, as after the latter the patients remain more completely quiescent for a longer period. I have found that lumbar puncture in the lateral position is much less likely to arouse the patients than sitting them over the end of the table, and I am inclined to avoid the testing of analgesia with a pin, as sufficient information can almost always be obtained from the relaxation of the muscles.—I am, Sir, yours faithfully,

Queen Anne-st., W., Jan. 23rd. CHARLES F. HADFIELD.

THE PRESENT POSITION OF ORGANO-THERAPY.

To the Editor of THE LANCET.

SIR,—Who, I wonder, is profited by Prof. Swale Vincent's periodical scoldings of the clinical endocrinologist.[1] Certainly not the latter, for we, the culprits, are serenely impenitent. Almost certainly not the former, because he is depressingly negative. And surely not the medical public, for no public is ever influenced by unconstructive scolding. After all, what does it matter if we do allow our imaginations occasionally to run riot? Endocrinology is still very far from being an exact science, and guesses at the truth are no more reprehensible in this department than they are in any other sphere where experiment and speculation have walked profitably hand in hand. Did bacteriology rise fully equipped out of Pasteur's head, like Athena out of Jupiter's? Or did radiology out of Rontgen's? And if not, are we expected to believe that there were no vain imaginings in the evolution of these sciences?

---

[1] THE LANCET, August 12th, 1922, p. 313, and Jan. 20th, 1923, p. 130.

Moreover, Prof. Swale Vincent, by his valuable contributions to endocrinology, has done his bit in stimulating that very enthusiasm which he is now so tireless in rebuking. It is a pity that he should be tiresome as well as tireless. Negative nagging is always a nuisance, but when it proceeds from one who has abundantly proved himself to be capable of better things, it becomes something in the nature of a tragedy. I am, Sir, yours faithfully,

Harley-street, W., Jan. 27th. LEONARD WILLIAMS.

"SOME THOUGHTS ON ENDOCRINOLOGY."

To the Editor of THE LANCET.

SIR,—Every new method necessarily passes through a period of criticism, and there are two main types of critics: (1) Those who criticise from the bedside or the laboratory, and (2) those who criticise from the arm-chair. The former are helpful to the criticised, and their criticism is constructive, because it is founded on experimental data; with the latter the reverse is true. The crucial test of any method is its use and not its hypothetical value; it must stand or fall by the results obtained from its practice, and the right of real criticism belongs only to those who have had experience.

As I am one of the gentlemen referred to in "A Physician's" letter in THE LANCET of Jan. 27th, I should like to draw the writer's attention to the following references: *Jour. Physiol.*, 1921, lv., 86, a method for estimating calcium; *Brit. Med. Jour.*, Oct. 29th, 1921, and May 20th, 1922, clinical papers on calcium and parathyroid therapy. Finally, if he will divulge his name and address—privately as he prefers it—I shall be pleased to send him in due course a reprint of a method of standardising parathyroid preparations which I hope to publish in the near future.

I am, Sir, yours faithfully,
H. W. C. VINES, M.D.

Christ's College, Cambridge, Jan. 30th, 1923.

THE THEORY OF VISION.

To the Editor of THE LANCET.

SIR,—There is no subject in which a revision of the statements made is more required than that of vision. Theories are given as facts when there is very little to support them except misstatements. This is particularly the case with the theory that supposes that the rods are percipient elements for perception in a dim light whilst the cones are the percipient elements in daylight. This theory is a very irrational one, for it is difficult to conceive an element stimulated by the decomposition of a photochemical substance which is excited by a weak light and not more strongly by a brighter light. What is the supposed function of the rods during the day-time? Apart from the numerous facts against this theory, it will be found that it is supported almost entirely by misstatements—namely: (1) That certain animals have only cones and others have only rods; (2) that the periphery of the retina is colour-blind; (3) that the eye is totally colour-blind in dark adaptation; (4) that the Purkinje phenomenon and the recurrent image are not found with the fovea. 1. Though I have examined numerous collections I have never been able to find any animal with only rods or only cones, neither have I found anyone who has seen such a retina. The tortoise is the most quoted, it is stated only to have cones; the rods and cones in the retina of the tortoise are as clearly defined and distinct as in the human retina. 2. The periphery of the retina is not colour-blind, when colours of sufficient intensity are used. The reader can test this for himself with a doctor's red lamp. He will find he can see it as red to the extreme periphery. 3. In dark adaptation the eye is not totally colour-blind; those interested in the subject should read the masterly paper by Burch on "Colour Vision by Very Weak Light."[1] Lately I have found that the colour of the yellow spot may be demonstrated by weak light. If three white discs, each two inches in diameter, be fastened on a black ground in a dimly-lighted room, in a line with an interval of two inches between them, on viewing them so that the centre one falls on the yellow spot, this appears darker and orange-yellow, whilst the two others appear bright bluish-white. There is no scotoma corresponding to the rod-free portion of the macula which is equal to a visual angle of about 3°. 4. The Purkinje phenomenon and recurrent image are found with the fovea.

All the facts point to the visual purple being the visual substance and that vision takes place by stimulation of the cones through its decomposition by light.—I am, Sir, yours faithfully,

London, Jan. 26th, 1923. F. W. EDRIDGE-GREEN.

"THE GOLD HEADED CANE."

To the Editor of THE LANCET.

SIR,—The brevity of your reviewer's note on my new edition of the above is my excuse for begging a modicum of your space. The book was issued under great disadvantages, inasmuch as the (1920) stereotyped issue of the New York editions of 1915 was placed on the English market a few months ago, with the imprint of the Oxford University Press upon its title-page. I had hoped that THE LANCET would give me a helpful notice. Your reviewer's objections to the footnote on page 30, that "the Radcliffe Library is perhaps the most beautiful building in Oxford," should be addressed, not to me, but to Dr. Macmichael, who wrote those words just 96 years ago. I will only remark that they were not criticised in the previous review in THE LANCET of Nov. 4th, 1922. As to Knightsbridge, its vaunted salubrity, and its place-names, my statement was originally published in "the History of St. George's Hospital," and for 13 years it has been unchallenged. It was written after many years of research in every pertinent MS. record I could find in the Chapter House at Westminster, at St. George's, and the public record offices; and after revision and correction of the text by my friend, the late Colonel Prideaux, the recognised authority on the topography of Knightsbridge. You will perhaps allow me, since your reviewer does not mention them, to draw attention to the splendid paper, type, and photogravure portraits, with which the publisher (Kimpton) has embellished the volume.

I am, Sir, yours faithfully,

Randolph-crescent, W., Jan. 28th. GEORGE C. PEACHEY.

---

[1] Proceedings of the Royal Society, vol. lxxvi., B, p. 199.

DONATIONS AND BEQUESTS.—The Manchester Royal Infirmary has received a donation of £1250 from Messrs. Peel and Co., Ltd., Manchester; £420 for the Bowlers' Cot Endowment Fund; £369 from Radcliffe Charities Committee; a legacy of £500 from the late Miss M. A. Morgan; £200 from the late Mr. Charles Duckworth; and £50 from the late Mr. James Lonsdale. Ancoats Hospital, Manchester, has received for the Nurses' Home Building Fund nearly £1200, including £500 from the Right Hon. Lord Cawley; Messrs. Holland, Ltd., £200; Messrs. Hardman and Holden, Ltd., and Hydes Brewery, £100 each. Sir Thomas Rowbotham has given £1000 to the governors of the Stockport Pendleton Charity.

Obituary.

HUNTER FINLAY TOD, M.D., B.CH.CAMB., F.R.C.S.ENG., L.R.C.P.LOND.,

SENIOR AURAL SURGEON AND LECTURER IN AURAL SURGERY, LONDON HOSPITAL.

Mr. Hunter F. Tod, aural surgeon to the London Hospital, died in pathetic circumstances at that institution on Jan. 13th. For some time past he had suffered from a laryngeal condition whose malignancy declared itself a short time ago; realising that an operation was imperative, he chose to be operated upon in one of his own wards in the hospital, and after the operation he went to the Riviera to recuperate. But to him the fact was soon clear that recovery was impossible, and he returned to the London Hospital, preferring, as he said, to die in his own wards among his friends and colleagues.

Hunter Tod was the second son of the late Mr. David Tod, J.P., of Eastwood Park and Hartfield, Renfrewshire, Scotland. He was educated at Clifton and Trinity College, Cambridge, graduating in arts with first-class honours in natural science in 1892, and in medicine and surgery in 1896, in which year he also obtained the English double qualification. His career at the London Hospital as a student was a successful one in every way. He won the surgical scholarship in 1895, was house surgeon under Sir Frederick Eve and house physician under Sir Stephen MacKenzie and Schorstein, and his colleagues in residence included Mr. Russell Andrews, Sir Hugh Rigby, and Sir Neville Howse, V.C. As a student at the London hospitals he gained honours in sports as well as work, being a prominent exponent of Rugby football.

In 1898 he became a Fellow of the Royal College of Surgeons of England, and having determined to take up aural surgery, he studied for a year at Halle, and became house surgeon to the Throat Hospital in Golden-square. This was followed by a further prolonged course of study under the great aural surgeons of Leipzig, Vienna, and Berlin. Although fond of amusement, he worked hard, and acquired a sound theoretical and practical knowledge of his subject. Returning to London in 1901, success came to him rapidly. At the end of that year he was appointed assistant aural surgeon to the London Hospital, a post which was specially made for him, as he was apparently considered too young to become full aural surgeon at once, and a few months later he was appointed aural surgeon to the Children's Hospital, Paddington Green. Within two years he was elected full aural surgeon to the London Hospital, which appointment he held until his death, having had his term of office extended by the committee of management, an almost unique honour. Success also came rapidly in private practice, and he had many distinguished patients. Amongst other positions he was president of the Otological Section of the Royal Society of Medicine during the present session, and had been examiner to the Royal Army Medical College, and a member of the Special Aural Board of the Ministry of Pensions. He was the author of a manual of "Diseases of the Ear," published in 1907. This was a practical book supplying the needs and requirements of students and practitioners alike. In addition to his contributions to medical journals he wrote the article on Diseases of the External Ear and Tympanic Membrane for Allbutt's "System of Medicine," that on Operations upon the Ear for Burghard's "System of Surgery," those on Diseases of the Tympanic Membrane, Adenoids, and Nasal Obstruction for the "Practical Encyclopædia of Medicine and Surgery," and on Acute Inflammation of Middle Ear for Latham and English's "System of Treatment."

Mr. Lambert Lack, who was closely associated with Hunter Tod throughout his professional life, writes as follows: "Hunter Tod had a very distinct but complex personality, one easily misunderstood by those who knew him but little. Those who knew him intimately recognised that he had solid qualities of sterling merit. First, one soon discovered that 'he knew his work.' Blessed with keen intelligence and a good memory, he had made full use of his exceptional opportunities, had worked hard at his profession and mastered it. His opinion on a difficult case was to be trusted, his methods of treatment were sound, he was a skilful and safe operator. Withal he took endless trouble with his patients and was kindliness itself. His reputation among his colleagues may be judged by the unhesitating way they sought his aid when they were themselves in need of aural treatment, and in whatever danger placed themselves unreservedly under his care. Secondly, one must mention his love for the London Hospital. He was an out-and-out 'Londoner,' and eager that the hospital should be first in every way. In his own specialty he strove to give the 'London' the best aural department in the world, and many of the advantages enjoyed there to-day are the direct results of his enthusiasm and pertinacity. His efforts might meet with rebuff, even ridicule, but this rather spurred than deterred him. He was a man with whom one was proud to work, quite free from mean or mercenary motives, loyal and generous in his dealings with his colleagues and his patients, a man who lived right up to the high ideals of his profession although he might never mention them. He wrote little, but that little was good. A small, readable, and reliable text-book on Aural Surgery, some contributions on aural subjects to various systems of medicine and surgery, one or two valuable monographs and reports on cases in various journals. His writings never savoured of advertisement. One could say much more of his solid worth, yet of his lighter side, almost of his foibles, one must also write. Indeed it was these that endeared him to his friends. None of his colleagues possibly but were ruffled on occasions by his mercurial temperament, but none bore him enmity, nor did he bear enmity to any, however acutely he might have differed from them at times. Of short stature, with slight boyish figure, always immaculately, even smartly dressed—he was certainly pleased at being considered the best dressed man on the 'London' staff—his quick, almost jerky movements, vivacious speech, his manner grave or gay by rapid turn, his almost boyish enthusiasm throughout his life, made him appear years younger than he was, and it is hard to believe that he had reached or could ever reach middle age, although he was over 50. He was young in mind and body and full of the *joie de vivre.* His tastes for pleasure and amusement were catholic, and he was an excellent companion. As his means were never too restricted he probably got as much enjoyment out of life as most men. His love and admiration of his hospital continued constant, and it was to the 'London' that he turned when nearing the end of his long and painful illness to seek what alleviation was possible. It was a great comfort to him to be received there, and he constantly expressed his gratitude to his nurses and colleagues for their devoted care. Throughout his illness he maintained a remarkable courage and an almost strange cheerfulness."

In 1909 Hunter Tod married the daughter of Dr. Stanley Rendall, and his family life with his wife and four children was ideally happy. To them we tender our profound sympathy. It is not as a great pioneer, but as a teacher and practitioner of aural surgery, with a lovable personality, whose work and example did much to raise and nothing to lower the highest ideals of his profession, that he will be remembered and missed.

JOHN WILLIAM BALLANTYNE, M.D., C.M., F.R.C.P. EDIN., F.R.S.E.,

EXTRA PHYSICIAN, ROYAL MATERNITY HOSPITAL, EDINBURGH.

Dr. John William Ballantyne, well-known alike as a gynæcologist and an enthusiastic worker in the field of antenatal physiology, died in Edinburgh on Jan. 23rd in his sixty-second year. He was born at Eskbank, Dalkeith, where his father kept a nursery garden, and received his early education at Bonnington Park School, Peebles, proceeding to the George Watson College, Edinburgh, before he entered the University. He was a successful student, and when he graduated M.B., C.M. in 1883 he won the Buchanan scholarship. His interest in gynæcology was manifested from the beginning, and in 1885 he was appointed senior assistant to the Professor of Midwifery in the University, a position which he held for five years. In 1887 he took the M.R.C.P. Edin., and a year later received the Fellowship. In 1889 he proceeded to the M.D. degree, obtaining the gold medal for his thesis, when he won also the Gunning-Simpson prize. From 1890 to 1894 he was lecturer on diseases of infancy in the School of Medicine of the Royal Colleges at Edinburgh, during which time the Cullen prize of the Royal College of Physicians was awarded to him.

Dr. Ballantyne was appointed in 1901 lecturer on midwifery and gynæcology to Surgeons' Hall, Edinburgh, and later to the same position in the School of Medicine for Women. In 1904 he was appointed physician to the Royal Maternity Hospital and two years after to the lectureship on midwifery in the University, and to the post-graduate vacation courses in medicine. At the time of his death he was extra physician to the Royal Maternity Hospital, Edinburgh, and physician in charge of the antenatal department and consulting physician for diseases of women in the Western Dispensary. A fellow, late president, of the Edinburgh Obstetrical Society, and hon. fellow of the Glasgow Obstetrical and Gynæcological Society, Dr. Ballantyne was also a fellow of the American Association of Obstetricians and Gynæcologists, and an hon. member of the American Child Hygiene Association.

His numerous contributions to the literature of the special department of medicine in which he was working possessed a marked literary style and showed a keen appreciation of the correct use of the English language. Between 1892 and 1905 he edited Green's "Encyclopædia and Dictionary of Medicine," in 10 volumes, which has gone through two editions, and the second edition of the "Encyclopædia Medica," in 15 volumes, which is now in course of reissue. He was editor of the Transactions of the Edinburgh Obstetrical Society, and his works include an "Introduction to the Diseases of Infancy," "Diseases of the Fœtus," "Manual of Antenatal Pathology and Hygiene," "Essentials of Obstetrics," and "Essentials of Gynæcology." He was also joint author of "Structures in the Mesosalpinx."

Dr. J. S. FAIRBAIRN writes:

The name of John William Ballantyne will be associated in the minds of his professional brethren and all workers in the public health service in this country with the part he played in introducing the thorough and systematic observation of pregnancy, now commonly known as "antenatal supervision." Ballantyne himself preferred the term "prematernity," and urged the formation of a prematernity department with prematernity beds in all lying-in hospitals, and by his enthusiasm for this side of obstetrical practice obtained the money to inaugurate the first ward of this kind in the Edinburgh Maternity Hospital. Like all pioneers who do great work, he was not satisfied that he himself should have a department in his own hospital, but in season and out of season by his persistence in advocating the need for, and the value of, a study of pregnancy, forced his view on the profession and led to the remarkable development of this side of obstetrics which is so characteristic a feature of present-day practice.

Ballantyne appears to have reached his objective by a somewhat roundabout route, and not by the straight road of preventive medicine. His earlier excursions were made in the direction of the antenatal pathology of the fœtus, and he became, by his investigations into developmental errors and congenital malformations, the highest authority of his day on teratology. His books on the diseases of the fœtus and antenatal hygiene are a monument to his industry and erudition. From trying to determine the maternal disturbances that might affect conception, and through his interest in investigating the factors that lead to deformity and death of the fœtus, he arrived at the necessity for prematernal care and the observation of the pregnant woman; his propaganda in this direction was the chief stimulus to the present-day insistence on antenatal hygiene.

In spite of his concentration on rare and unusual congenital conditions, Ballantyne had nothing of the narrow specialist's outlook on medicine, but rather the open survey of the general practitioner. Besides obstetrics and gynæcology he had extensive knowledge of the diseases of infancy; his editorship of the Encyclopædia Medica showed his insight also into general diseases and accidents, and his knowledge of their treatment and prevention. Latterly, his work became more that of a writer and publicist than a practitioner, and his name became known to a yet wider circle because his energies were by no means confined to the subjects he had made his own.

At the time of his death Dr. Ballantyne was engaged in a very important work for the Medical Research Council—namely, that of putting together the results of a systematic examination of a large number of cases of dead-birth carried out in different centres by different investigators, and much valuable information was expected as a result of his wide knowledge of the subject being brought to bear on this mass of material. By his death this country has lost not only a man of wide learning, but one who has had a remarkable influence on the health service of the country.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lt. G. Aubrey to be Surgeon Lt.-Comdr.

Actg. Surg.-Lts. (Dental): J. L. Edwards, J. M. Park, W. T. L. Douglas, and S. E. Brown to be Surg.-Lts. (D.).

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. A. W. N. Bowen retires on ret. pay and is granted the rank of Col.

Lt.-Col. H. G. F. Stallard retires on ret. pay.

Maj. R. G. H. Tate relinquishes the temp. rank of Lt.-Col. on ceasing to be empld. as Asst. Dir. of Pathology and Hygiene.

ARMY RESERVE OF OFFICERS.

Army Dental Corps.

Capt. D. R. B. Grant, late Spec. List, to be Capt.

TERRITORIAL ARMY.

The undermentioned, having attained the age limit, are retired, and retain their rank except where otherwise stated: Lt.-Cols. Sir J. K. Fowler, H. P. Hawkins (Bt. Col.), S. P. Phillips (Bt. Col.), and N. Dalton; Majs. Sir F. W. Mott (Bt. Lt.-Col.), A. P. Luff (Bt. Lt.-Col.), Sir J. Bland-Sutton (granted the rank of Lt.-Col.), W. A. Turner (granted the rank of Col.), W. G. Spencer, W. E. Wynter, J. E. Lane, and A. F. Voelcker; Capts. C. R. Box (Bt. Maj.), V. W. Low (granted the rank of Col.), W. Turner (granted the rank of Maj.), E. M. Corner (granted the rank of Maj.), Sir J. F. H. Broadbent, G. J. Jenkins, H. Low, J. S. Fairbairn, J. H. Fisher, J. P. Hedley, Z. Mennell, A. E. Russell, F. J. Poynton, J. Murray, T. H. Kellock, H. B. Shaw, H. Johnson, H. S. Clogg, F. W. Tunnicliffe, W. d'E. Emery, D. H. de Souza, R. Knox, R. C. Thomson, W. B. L. Trotter, A. Kingsford, R. R. Cruise, W. Harris, A. Latham, C. Gibbs, A. H. Evans, and J. S. Collier.

ROYAL MEDICAL BENEVOLENT FUND GUILD:

FESTIVAL DINNER.

OVER 400 hostesses and guests assembled at the Hyde Park Hotel on Jan. 30th, the occasion being a festival dinner organised by the Royal Medical Benevolent Fund Guild. Lady Barrett presided over a gathering composed of small intimate parties at tables which were so well grouped that all could hear distinctly the admirable short speeches in which the objects of the Guild were detailed. The Chairman explained that the Guild attempted to supplement the doles allocated by the Fund by grants for educational purposes, in order that orphans and dependents of unfortunate medical men and women should be equipped to help themselves. She gave examples of the kind of help given, such as the placing of the youngest (aged 5) of a family of 10 in an orphan's school and the training of a youth as a radiological assistant. This work, as well as the provision of clothes and coal in necessitous cases, was hampered constantly by lack of funds.

A Plea for Support.

Mr. W. B. Maxwell, starting with apt similes and engaging anecdotes, developed a cogent plea for support of the Fund and Guild, as a deferred debt owed by the public to the medical profession for such services rendered as could never be adequately paid. Dr. Janet Lane-Claypon followed, dwelling especially on the educational side of the work done by the Guild. The medical profession and those friendly towards it should see that none of its daughters should be allowed to drift into the hopeless position of the untrained unmarried woman with no means of support. Sir Douglas McGarell Hogg, whose interest in the Guild had been aroused by Sir Alfred and Lady Fripp, then crisply outlined a scheme which had been suggested and supported by the committee of the Guild for enlarging the scope of the work. Each of the great medical schools of the United Kingdom had a special tradition of loyalty to one or more medical men whose great names were associated with the school. The establishment of scholarships bearing the names of illustrious pioneers by those now connected with a medical school would be a fitting and a perpetual memorial. Those doctors commemorated in this way need not, however, be of world-wide or even of local fame; no more suitable memorial for anyone who was beloved by colleagues, patients, or friends could be imagined. Two scholarships existed already, one in memory of the late Dr. Vernon Jones, and the other in memory of the wife of Sir John Phillips, and Sir Douglas Hogg asked that many more should be created. The Bishop of Chester, in commending this scheme, spoke of the wonderful loyalty of a medical man to his own hospital, which should lead to the success of this project. The toast of the guests having been proposed by the Chairman, Lord Riddell responded with wit and grace on their behalf. In looking through the subscription lists of hospitals he had been struck by the number of doctors among the subscribers. The public ought to aid the profession in turn.

The Profit to the Fund.

The Chairman announced £1288 clear profit for the Fund as the result of this dinner, £120 had already been received from the sale of stamps for the golf competition organised by Lady Rigby and £105 in connexion with a portrait offered to the Guild by Mr. Ralph Peacock. In addition, scholarships on the lines suggested had just been offered—one by Sir Gilbert Wills in memory of his father, and the other in memory of Richard Bright of Guy's Hospital. It was hoped, said the Chairman, that the figure for the dinner fund would still be raised.

Medical News.

UNIVERSITY OF OXFORD.—At a meeting of the electors held on Jan. 16th Dr. Rudolph Albert Peters, Fellow of Gonville and Caius College, Cambridge, was elected Whitley Professor of Biochemistry.—The remaining Degree Days in the present term are: Saturday, Feb. 17th, Thursday, March 8th, and Saturday, March 24th.—Examinations for scholarships in natural science are announced for the following dates: March 13th, at Keble College; March 20th, at Queen's College; and March 20th, at Merton, Exeter, New, Brasenose, Corpus Christi, and Wadham Colleges.—Hertford College: Mr. Robert d'Escourt Atkinson has been elected to a Fellowship for Research.

UNIVERSITY OF LONDON.—A meeting of the Senate was held on Jan. 24th, Mr. H. J. Waring, the Vice-Chancellor, being in the chair. Sir Sydney Russell-Wells was reappointed representative of the University on the General Medical Council for 1923–24. The following Doctorates were conferred: D.Sc. in Embryology, Mr. G. S. Sansom; D.Sc. in Physiology, Dr. G. V. Anrep.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia of the College was held on Jan. 25th, Sir Humphry Rolleston, the President, occupying the chair.—A report was received from the Censors' Board, and it was resolved in accordance with By-law CXC.:—

> "That David Arnold Chaning Pearce be declared to be no longer a licentiate of the College; that he forfeit all the rights and privileges of a licentiate; and that his name be expunged from the list of licentiates—during the pleasure of the College."

The following were admitted as Members of the College: Drs. Christopher H. Andrewes, Edwin B. Ash, Lindsey W. Batten, Winfred K. Beaman, Gerald T. Burke, Edwin G. B. Calvert, Maurice Coburn, Lawrence P. Garrod, Frank S. Hansman, Henry L. Heimann, Kenneth S. Hetzel, Thomas A. Hughes, Claude B. Levick, Michael H. Southwick, and John O. Thomas.

Licences to practise physic were granted to 91 candidates, who had conformed to the by-laws and regulations and passed the required examinations. The following are the names and medical schools of the successful candidates:—

W. F. T. Adams, Cambridge and St. Bart.'s; H. S. Allen, Cambridge and St. Thomas's; C. C. P. Anning, Cambridge and Leeds; C. H. Atkinson, Guy's; A. Barker, Cambridge and London; L. J. Bendit, Cambridge and Univ. Coll.; J. C. Bennett, Adelaide and London; J. Bernstein, Leeds; F. E. G. Bonnalie, Cambridge and Guy's; C. C. Bradsworth, Birmingham; Marjorie Broadbent, Royal Free; B. Broman, Manchester; Mary G. Brown, Royal Free and London; Violet W. Brown, Royal Free and St. Mary's; T. B. Butcher, St. Mary's; G. H. Caiger, Cambridge and St. Bart.'s; Dorothy M. Campbell-Meiklejohn, Univ. Coll.; Marjorie F. Cartledge, Royal Free and St. Mary's; F. S. Coleman, St. Bart.'s; Annie E. Connan, Royal Free; Isidore H. Cowan, Leeds; B. A. Crook, Bristol; Dorothy A. D. Cropper, Cambridge and King's Coll.; J. E. D. Crozier, Cambridge and St. Thomas's; D. B. D'Alwis, Ceylon and Middlesex; Mary L. Davies, St. Mary's; V. R. J. de Boissiere, Guy's; Gertrude M. de Souza, Madras and Royal Free; W. Edwards, Cambridge and St. Bart.'s; J. M. Evans, Bristol; R. H. Evans, Cardiff and London; R. R. Foote, St. Bart.'s; H. S. Forbes, Univ. Coll.; L. Forman, Guy's; C. A. H. Franklin, St. Thomas's; Martha Griffith, Charing Cross; P. Hack, Guy's; Margaret C. N. Hadley, London; Kathleen M. D. Harding, Royal Free and St. Mary's; C. F. Harris, St. Bart.'s; G. Henly, Birmingham; N. G. Hill, London; R. J. Hooker, Guy's; M. Jackson, Cape and Guy's; J. Jensen, Copenhagen and London; H. V. Jessop, Birmingham; R. Keene, St. Bart.'s; E. C. K. Kenderdine, Bristol; J. P. Kies, St. Thomas's; Kathleen H. B. King, London; L. Lawn Cambridge and St. Thomas's; C. P. Ledward, Univ. Coll.; J. T. Linklater, Cape and Guy's; J. H. M. Lloyd, Guy's; Alison N. Macbeth-Morland, Lausanne and Univ. Coll.; H. J. Malkin, Univ. Coll.; Grace E. Mizen, Charing Cross; M. S. H. Mody, Bombay and Middlesex; G. O. Montgomery, Univ. Coll.; G. S. Morgan, St. Bart.'s; L. Morgenstern, Manchester; H. V. Morlock, St. Bart.'s; R. M. Morris, Cape and London; H. Mould, Univ. Coll.; E. S. Page, Cambridge and St. Thomas's; Ruth N. Parker-Gray, Royal Free; Emily C. N. Paterson, King's Coll.; H. J. Plowright, Guy's; J. A. L. Roberts, Bristol; B. W. Roffey, St. Mary's; M. Rose, Leeds and Guy's; R. Salib, Manchester; Eva M. Sansom, Royal Free; H. B. Shaw and A. G. Silver, Middlesex; Helen O. Skelton, Royal Free; Agnes B. Smith, King's Coll.; F. E. Smith, Middlesex; R. M. Somerset, Sheffield; H. J. H. Spreadbury, Bristol; H. A. Surial, Cairo and Birmingham; G. B. Tait, Cambridge and St. Bart.'s; G. Tate, Edinburgh and King's Coll.; G. D. Thomson and T. R. Thomson, Cambridge and St. Thomas's; B. M. Tracey and W. R. Ward, St. Bart.'s; H. W. M. Williams, Cardiff and St. Bart.'s; R. N. P. Wilson, Cambridge and Leeds; Marguerite A. Xavier, Royal Free; and James Yates, Manchester.

Diplomas were granted jointly with the Royal College of Surgeons of England as follows: In Public Health to 24 candidates,[1] in Tropical Medicine and Hygiene to 13 candidates,[1] in Psychological Medicine to 13 candidates,[1] and in Ophthalmic Medicine and Surgery to the following 13 candidates :—

> Conjuvaram Abbu, Madras and Roy. Lond. Ophth. Hosp ; Charles Gustav Berge, Sydney, Roy. Lond. and Roy. West. Ophth. Hosp. ; Gerald Edward Breen, Dublin and Roy. Lond. Ophth. Hosp. ; George Arthur Brookes, Sydney, Norwich, and Roy. Lond. Ophth. Hosp. ; Daniel Davies Evans, Cambridge and St. Bart.'s ; Najmudin Kamrudin Gangriwala, Bombay and Roy. Lond. Ophth. Hosp. ; Joshua Keyms, Cork and Roy. Lond. Ophth. Hosp. ; Edward John McGuinness, Sydney and Roy. Lond. Ophth. Hosp. ; Murray Joseph Moher, Ontario, Wolverhampton and Mid. County Eye and Roy. Lond. Ophth. Hosp. ; Rowland Jordan Gore Armstrong Pittar, Sydney and Roy. West Ophth. Hosp. ; Andrew McKie Reid, Liverpool and Roy. Lond. Ophth. Hosp. ; Mukundrai Dolatrai Thakore, Edinburgh and Leeds ; Joseph Deane Woolworth, Memphis, U.S.A., and Roy. Lond. Ophth. Hosp.

Dr. W. S. Lazarus-Barlow, Sir John Broadbent, Dr. T. W. Eden, and Sir George Newman were elected councillors, on the nomination of the Council, to take the places of Drs. Lauriston Shaw, Copeman, Chaplin, and Blacker, who retired by rotation.—Dr. Herbert Spencer and Dr. Raymond Crawfurd were elected members of the Library Committee, on the nomination of the Council, to take the places of the late Sir Norman Moore and the late Sir James Galloway.—On the invitation of the Vice-Chancellor of the University of London, Sir William Hale White and Dr. R. A. Young were appointed to represent the College at a conference concerning the courses of instruction provided by medical schools.—Leave to reproduce the portraits of certain physicians in a publication intended to celebrate the centenary of THE LANCET was granted to the Editor of THE LANCET.—The President was appointed as a delegate to attend the celebration of the 800th anniversary of the foundation of St. Bartholomew's Hospital (June 5th–7th next).—Dr. R. O. Moon was appointed to represent the College at the commemoration of the centenary of Jenner organised by the Académie de Médecine (Paris).—Permission was granted to the curator of the Wellcome Historical Museum to borrow the horn of the cow from which Jenner first took his vaccine, for an exhibition in commemoration of the centenary of Jenner.—The President announced that the Council had appointed Lieut.-Colonel William Glen Liston, C.I.E., M.D., to deliver the Milroy Lectures in 1924.—Sir Francis Champneys was appointed, on the nomination of the Council, a representative of the College on the Central Midwives Central Board.—The registrar gave notice that he will move, at a future meeting of the College, certain alterations in the by-laws necessitated by the new regulations concerning the examinations for the licence.—*Lloyd Roberts Lectures :* On the suggestion of the President it was resolved that the nomination and appointment of the lecturer be delegated to the Censors' Board.—A report was received from the representative of the College on the General Medical Council, on the proceedings of the Council at their session in November last.—A report, dated Nov. 10th, was received from the committee of management reporting that Mr. H. J. Waring had been to Cairo to act as visitor of the Board at the examination of the Egyptian School of Medicine, Cairo, in January.—A further report, dated Dec. 19th, was received from the committee of management dealing with the new regulations drawn up by the General Medical Council for Diplomas in Public Health, which are to come into force in January, 1924.

INCORPORATED VERMIN REPRESSION SOCIETY AND COLLEGE OF PESTOLOGY.—The fourth annual dinner of this Society (the first since the establishment of the College) was held at the Café Royal, Regent-street, on Jan. 25th, Colonel the Hon. Cuthbert James, M.P., being in the chair. After the loyal toast had been given, Colonel James proposed the health of the Society coupled with that of Sir James Crichton Browne, F.R.S., the principal guest of the evening and first president of the Society, and in the course of a short speech referred to the need for enthusiasm amongst the public in the matter of vermin repression. The cost of repressive measures, and the name of the Society had, he said, gone somewhat against the latter in efforts to interest the House of Commons in the Society's work, but he foresaw a great future for the work of vermin repression. The individual farmer, particularly the small ex-tenant farmer who was now an owner, was at present frequently unable to undertake any expense in that direction ; moreover, he (the farmer) naturally objected to isolated action, for rats from neighbouring property merely overran his land again as soon as he had cleared it. The Government must be interested in agricultural vermin—in the rat, the mouse, and the vermin of fruit and hops and potatoes—and above all, the public must be educated. Dr. Nathan Raw briefly seconded the toast. Sir James Crichton-Browne, replying, referred to his continous connexion with the Society from its beginning, under the name of the Vermin Destruction Society, in 1907. Although the Society had three times changed its name it had held to its aims, and had now reached a stage which would, he hoped, be permanent, for its reconstituted form would appeal to many elements of society ; pestology covered every type of vermin, but the rat was the subject of primary consideration. He referred to Dr. Andrew Balfour's recent monograph in the last number of *Parasitology*, in which, although the effort to sterilise rats by means of a preparation had proved unsuccessful, much valuable research work was recorded. Not only zoology, but bacteriology, mycology, and kindred subjects must be included in the scope of the Society's work ; the Pasteur Institute had been successful in widespread destruction of voles in France, and he looked forward to the time when an absolutely safe bacterial virus would be available against rats. As a scavenger the rat did more harm than good ; a very small contingent of rats was all that was required for purposes of scientific inquiry. The hoped-for holocaust would one day be successful, and our descendants might have to take their children to a natural history museum to see a rat. This type of vermin had not always existed in England ; the black rat appeared during the twelfth century, and the brown rat about 1730. In 1610 repressive measures were already found to be necessary ; the Privy Council of Scotland in that year granted permission to certain Italians to live in Scotland and to make sacks and machines for the taking of "ratten and mice." Steady, sustained, and simultaneous action was needed ; many farmers and householders did not know how to go about the work. A certain number of unemployed men might be given useful work in ratting in country and slum districts ; he concluded by commending this suggestion to the Board of Agriculture and to the Ministry of Health. Mrs. Bewick then spoke of her personal experience in ridding property of rats, and emphasised the need for all rubbish likely to attract rats to be buried or burned. Mr. Bruce Wolfe, representing the cinema industry, explained that whilst the cinema firms were very willing to help the Society's cause, the only way in which they could do it was to show films which would pay, films which everybody could understand, and in which the instruction was well wrapped up in a popular way. Mr. A. E. Moore (hon. director of the Society) and Dr. C. W. Hutt (medical officer of health, Borough of Holborn) also briefly addressed the company.

MIDDLESEX HOSPITAL MEDICAL SCHOOL.—An Emeritus lecture will be delivered by Sir Richard Douglas Powell, at 3 P.M., to-day, Friday, Feb. 2nd, on Aortic Regurgitant Disease Regarded Specially from a Prognostic and Life Assurance Point of View. Sir John Bland-Sutton will deliver an Emeritus lecture at 3 P.M., on Tuesday, May 1st, the subject of which will be announced later.

LYCEUM CLUB DINNER.—A well-attended dinner was held at this club on Jan. 24th. The medical "Guests of Honour" included Dr. C. Hubert Bond, Dr. F. H. Edwards, Sir Frederick Mott, Dr. Bedford Pierce, and many others. After dinner the chairman, Mrs. N. Shelley, called upon Dr. Montague Lomax to give an address on Lunacy Reform. Dr. Lomax spoke at considerable length, giving instances which he believed to be well authenticated of ill-treatment of patients by nurses, and reiterated his plea for the establishment of a Royal Commission to investigate the charges made. Many guests, while cordially appreciating the hospitality of the club, expressed regret that there was unfortunately no opportunity for discussion of the questions raised.

WORKMEN'S COMPENSATION ACT : *Proposed Appointment of an Ophthalmic Specialist Medical Referee.*—The Secretary of State for the Home Department gives notice that he proposes to appoint an Ophthalmic Specialist Medical Referee under the Workmen's Compensation Act, 1906, for County Court Circuit No. 20, which comprises the Ashby-de-la-Zouch, Loughborough, Bedford, Bourne, Oakham, Stamford, Uppingham, Hinckley, Leicester, Market Harborough, Melton Mowbray, Kettering, and Wellingborough County Courts. Applications for the post should be addressed to the Private Secretary, Home Office, and should reach him not later than Feb. 17th.

MALARIA IN RUSSIA : THE NEED FOR QUININE.—Reports received from the Red Cross in Russia indicate that there are now some 8,000,000 cases of the disease in the Republic West of the Ural Mountains. In Georgia one-half of the population are affected and at the village of Sambourtale, near Tiflis, two-thirds of the total population have died of malaria. Much of the malaria is malignant. The disease is particularly prevalent in the famine-stricken Volga region and in the Caucasus. The Russian Medical Aid Committee has received an urgent request for quinine in large quantities and contributions may be addressed to Mr. A. Baker, Treasurer, Medical Aid Committee, 68, Lincoln's Inn Fields, London, W.C. 2.

---

[1] The names appeared in THE LANCET of Jan. 20th, p. 159.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Feb. 5th.

TROPICAL DISEASES AND PARASITOLOGY: at 8.30 P.M.
Paper:
Dr. Arthur Powell: Yaws—(*a*) The History of its Introduction into India. (*b*) Personal Observations on the Primary Lesion in 205 cases. (Illustrated by numerous photographs.)

DERMATOLOGY:
Members of this Section are cordially invited to attend the above meeting.

Tuesday, Feb. 6th.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)
Cases will be shown by—
Mr. H. A. T. Fairbank, Mr. R. C. Elmslie, Mr. Rowley Bristow, Mr. Gordon Pugh, and others.

PATHOLOGY: at the *Lister Institute* at 8.30 P.M.
Communications, &c.:
Dr. E. H. Lepper: Studies on the Twort-d'Herelle Phenomenon.
Dr. Z. Khaled: Para-enteric Infections in Egypt.
Dr. S. P. Bedson: Further Studies on Platelets.
Dr. J. A. Arkwright: Demonstration of Various "Species" of Rickettsia.

Wednesday, Feb. 7th.

SURGERY: at 5.30 P.M.
Papers:
Mr. G. Grey Turner: A case in which an Adenoma, weighing 2 lb. 2 oz., was successfully removed from the liver; with remarks on the subject of partial hepatectomy.
Mr. Garnett Wright: A case of Partial Resection of the Right Lobe of the Liver for Primary Carcinoma.
Members are invited to relate cases, or to show specimens, of partial resection of the liver for growths.

Thursday, Feb. 8th.

NEUROLOGY: at 8.30 P.M.
Paper:
Dr. E. D. Adrian: Disorders of Function in the Neurone.

Friday, Feb. 9th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)
Cases will be shown.

OPHTHALMOLOGY: at 5 P.M.
Clinical Meeting at the *Royal London Ophthalmic Hospital (Moorfields), City-road, E.C. 1.*
Cases: The following will be shown by—
Mr. Leslie Paton: Case of Herpes Ophthalmicus with Optic Atrophy.
Mr. F. Juler: Case of Cicatrisation in the Retina.
Miss Rosa Ford: Papillœdema and Homonymous Hemiopia (right upper quadrant).
Other cases will be shown.
NOTE.—The date of the Clinical Meeting has been altered from that previously announced.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
MONDAY, Feb. 12th.—8.30 P.M., Discussion on Psycho-Therapeutics, to be opened by Dr. E. Farquhar Buzzard, followed by Dr. William Brown, Dr. M. B. Wright, Dr. S. A. K. Wilson, Dr. David Forsyth, Dr. T. A. Ross, Dr. P. F. Barton, and others.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE POST-GRADUATE LECTURES, 1, Wimpole-street, W.
WEDNESDAY, Feb. 7th.—8.30 P.M., Mr. J. P. Lockhart-Mummery: Diverticulitis (illustrated).

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
MONDAY, Feb. 5th.—11 A.M., Mr. Maingot: Surgical Ward Cases. 12 noon, Mr. Simmonds: Applied Anatomy. 4 P.M., Dr. Archer: Demonstration of Analysis of Stomach Contents.
TUESDAY.—10.30 A.M., Dr. Paterson: Demonstration of Medical Cases. 12 noon, Dr. Burrell: Chest Cases. 4 P.M., Mr. Addison: Diagnosis and Treatment of Tuberculous Hip.
WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12 noon, Dr. Burnford: Pathological Demonstration. 4 P.M., Dr. Reece: Small-pox and Vaccination.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Department.
FRIDAY.—12 noon, Dr. Flett: Radiology. 2 P.M., Mr. Banks-Davis: Diseases of Throat, Nose and Ear. 3 P.M., Mr. Sinclair: Surgical Cases.
SATURDAY.—9 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10.30 A.M., Mr. Maingot: Surgical Pathology.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.
FRIDAY, Feb. 9th.—4.30 P.M., Dr. H. W. Barber: Demonstrations of Dermatological Cases.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: JAN.–MARCH, 1923.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Feb. 5th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Clinical Lecture: Dr. Aldren Turner.
TUESDAY, Feb. 6th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Cerebral Complications of Diseases of the Ear: Mr. Just.
THURSDAY, Feb. 8th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Lecture:—Painful Affections of the Upper Limb: Dr. Grainger Stewart.
FRIDAY, Feb. 9th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Polyneuritis: Dr. Collier.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

NEURO-PATHOLOGY.

MONDAY, Feb. 5th.—12 noon, Paths of Infection in the Nervous System: Dr. J. Godwin Greenfield.

N.B.—A Course of Lectures in the Anatomy and Physiology of the Nervous System will be given if there are sufficient entries for it.

The fee for the whole Course, including Anatomy and Physiology, is £12 12*s.*, but these Lectures may be taken separately for a fee of £4 4*s.* Course without Anatomy and Physiology Lectures will be £10 10*s.* Any part of the Course may be taken separately at a special fee. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.

C. M. HINDS HOWELL, Dean of Medical School.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Feb. 8th.—4 P.M., Dr. Nabarro: The Value of the Investigation of the Cerebro-spinal Fluid.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
THURSDAY, Feb. 8th.—5 P.M., Dr. J. L. Bunch: Some Unusual Forms of Skin Disease.

MANCHESTER ROYAL INFIRMARY. POST-GRADUATE LECTURES.
TUESDAY, Feb. 6th.—4.15 P.M., Sir William Milligan: Symptomatology of Brain Abscess.
FRIDAY.—4.15 P.M., Mr. J. Morley: Applied Anatomy of the Gastro-Intestinal Tract.

MANCHESTER, ANCOATS HOSPITAL. POST-GRADUATE LECTURE.
THURSDAY, Feb. 8th.—4.30 P.M., Mr. E. E. Hughes: Diagnosis of Swellings of Testes.

ST. MARY'S HOSPITALS, MANCHESTER. POST-GRADUATE LECTURE (at Whitworth-street West Branch).
FRIDAY, Feb. 9th.—4.30 P.M., Dr. Dougal: Hæmorrhage in Association with Pregnancy.

MANCHESTER FRENCH HOSPITAL, 24, Acomb-street, Whitworth Park.
THURSDAYS, Feb. 8th to March 29th.—4.30 P.M., Dr. A. C. Magian: Some Operations of Gynæcology.

Appointments.

DINGLEY, L. A., M.D. Lond., F.R.C.S. Eng., has been appointed Medical Referee under the Workmen's Compensation Act to the Dudley County Court in addition to the Walsall County Court.

EVANS DAVIES, G. OLWEN, Medical Officer and Public Vaccinator for Blaenau Festiniog and Maentwrog Parishes.

HADDEN, MARIE A., M.B., B.Ch. Dub., Assistant Medical Officer of Health, Ilford.

MACKAY, D., L.R.C.P. & S Edin., House Surgeon to Northern Infirmary, Inverness.

PARKER, H. G., F.R.C.S., L.R.C.P. Edin., to be one of the Medical Referees under the Workmen's Compensation Act for County Court Circuit No. 5.

PRIESTLEY, NORAH K., M.R.C.S., L.R.C.P. Lond., Second Assistant Resident Officer, Chelsea Infirmary.

ROBERTS, C. S. LANE, M.S. Lond., F.R.C.S. Eng., Gynæcologist, and HOWARD, DORIS M., L.M.S.S.A., Physician for Infant Consultations at the St. Marylebone General Dispensary.

TOWERS, A. K., M.D., Ch.B. Edin., L.R.C.P. & S. Edin., D.P.H., Medical Officer of Health, Jarrow.

Manchester Royal Infirmary: HICKSON, SYLVIA M., M.B., Ch.B. Manch., Assistant Medical Officer; ATKINSON, MARY W., M.B., Ch.B. Manch., Assistant Medical Officer, and ROTHWELL, ANNIE, M.B., Ch.B. Manch., Anæsthetist, Central Branch; BURKE, E. T., M.B., Ch.B. Glasg., reappointed Clinical Assistant to the Dermatologist.

Vacancies.

For further information refer to the advertisement columns.

Aylesbury, Royal Bucks Hospital.—Res. M.O. £150.
Bolingbroke Hospital, Wandsworth Common, S.W.—Res. M.O. £200.
Bristol Royal Infirmary.—H.P.'s and H.S.'s, &c. Each £120. Also Hon. Ophth. Reg.
Cambridge University.—Lecturer in Psychopathology. £175.
Derbyshire Education Committee.—Asst. School M.O. £600.
Derbyshire Hospital for Sick Children.—Res. M.O. £150.
Dumfries, Crichton Royal Mental Hospital.—Clinical Pathologist. £400.
Finsbury Dispensary, Brewer-street, Goswell-road, E.C.—P. £50.
Gloucestershire Tuberculosis Institution, Standish House, Stonehouse, Glos.—Asst. R.M.O. £300.
Gravesend Hospital, Kent.—H.S. £200.
Guildford, Royal Surrey County Hospital.—H.S. £150.
Ipswich, East Suffolk and Ipswich Hospital.—H.S. £125.
Liverpool, Royal Southern Hospital.—Res. Cas. O. £150. Also Two H.P.'s and Three H.S.'s. Each £100.
London County Mental Hospital Service.—Seventh Asst. M.O. £449.
London Homœopathic Hospital, Great Ormond-street, W.C.—Anæsthetist. £50.
London Lock Hospital, Dean-street and Harrow-road.—Surg. Reg.
Manchester, Monsall Fever Hospital.—Med. Supt. £750.
Middlesex Hospital, W.—Asst. (Therapeutic) for Radiological Dept. £500. Also S. and Asst. S.
Rochdale Infirmary and Dispensary.—Jun. H.S. £200.
Rosslynlee Asylum, Rosslyn Castle.—Asst. M.O. £300.
Rotherham Hospital.—Jun. H.S. £150.
Royal Eye Hospital, St. George's Circus, Southwark, S.E.—Hon. Asst. S. Also Clin. Assts.
Salford Royal Hospital.—Hon. Asst. Radiographer.
Sheffield, South Yorkshire Asylum.—M.O. £400.
Sheffield University.—Asst. Bacteriologist and Demonstrator in Pathology. Each £300.
Southampton, Royal South Hants and Southampton Hospital.—Jun. H.S. £150.
University of London.—External Examiners, &c. Chair of Anatomy. £1000.
Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Hon. P. or S. for Dis. of Skin.
Weston-super-Mare Hospital.—H.S. £150.
Worcester County and City Mental Hospital, Powick.—Jun. Asst. M.O. £300.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointment: Hornsea (York).

The Home Secretary proposes to appoint an Ophthalmic Specialist Medical Referee, under the Workmen's Compensation Act, 1906, for County Court Circuit No. 20, which comprises the Ashby-de-la-Zouch, Loughborough, Bedford, Bourne, Oakham, Stamford, Uppingham, Hinckley, Leicester, Market Harborough, Melton Mowbray, Kettering, and Wellingborough County Courts. Applications should reach the Private Secretary, Home Office, S.W., not later than Feb. 17th.

Births, Marriages, and Deaths.

BIRTHS.

GARROD.—On January 21st, at a nursing home, to Majorie Garrod (née Pierce), wife of Lawrence P. Garrod, of 65, Queen's-gardens, W. 2—a daughter.

REYNELL.—On Jan. 27th, at Nottingham-place, W., the wife of Dr. W. R. Reynell, of a daughter.

DEATHS.

DAVIS.—On Jan. 26th, at 35, Hamilton-terrace, N.W., Marcus John Davis, L.D.S. R.C.S. Eng., of 42, Harley-street, W., aged 64 years.

HARRIS.—On Jan. 23rd, at Hornsey-lane-gardens, Highgate, Alfred Edwin Harris, M.R.C.S., L.R.C.P., late Medical Officer of Health for Islington and Sunderland, in his seventy-third year.

MACARTHUR.—At Bank House, Golborne, on January 27th, in his sixty-third year, Benjamin Waite MacArthur, M.D., D.P.H., M.O.H. Golborne U.D.C.

SPEAR.—On Jan. 27th, at "Coppice Hanger," Pulborough, George Arthur Whitworth Spear, M.R.C.S., L.R.C.P.

WOOD.—On Jan. 24th, at Lisbon, suddenly, Thomas Wood, M.D., Eastwood, Ferry-road, Edinburgh.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

LITERARY INTELLIGENCE.—The merits of Lieut.-Col. R. H. Elliot's "Tropical Ophthalmology" have been widely recognised abroad, as translations into French and Spanish have already been published, and reviews have appeared in Japanese and Arabic as well as in many European languages. The publishers state that arrangements are now in progress for making the work available for German-speaking readers.

Notes, Comments, and Abstracts.

A PLEA FOR CHANGED METHOD IN THE TREATMENT OF THE TUBERCULOUS POOR

BY CLIVE RIVIERE, M.D., F.R.C.P. LOND.,
PHYSICIAN TO CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST.

No one conversant with the present-day treatment of tuberculosis among the working class will deny that the results are eminently unsatisfactory. The so-called "failure of sanatorium treatment" is, doubtless, but an inaccurate expression of this fact; inaccurate since it is well known to tuberculosis workers that the sanatorium does all that is allowed it under the circumstances, and the failure of treatment does not lie at its door. Let us inquire into the causes of this failure, and see whether there is not a better alternative to the present system at no more, or even less, than the present cost. For the sake of brevity and clarity, though at the risk of being unduly dogmatic, let us approach the matter by the elementary method of question and answer.

Our Present Method of Treatment.

Bed Treatment.

Q. What is our present aim in bed treatment?—*A.* To get rid of fever—that is, to reduce excessive and uncontrolled auto-inoculation, and to get the patient up and about as an afebrile case.

Q. What does this do for him?—*A.* It establishes "tolerance" against the toxins of disease, and so enables him to avoid excessive "focal reactions" whereby disease is activated and toxæmia renewed.

Q. When he leaves the sanatorium or hospital after two or three months' treatment is his disease arrested?—*A.* No, it is nearly always still active, as is shown by the physical signs, which change but little in so short a period.

Q. Do exercise and movement exert any effect on the diseased areas providing his "tolerance" prevents febrile and focal reactions?—*A.* Yes, they flood the lungs with blood—the pulmonary circuit being obliged to pass all blood which the systemic circulation sets in motion; also, the respiratory movements, becoming more ample and rapid, the diseased lung is stretched and exercised.

Q. Are active movements and intermittent flushing with blood approved treatment for active tuberculous lesions?—*A.* No.

Q. How long do patients spend in hospital or sanatorium?—*A.* Two or three months, sometimes less.

Q. How long does it take to cure pulmonary tuberculosis?—*A.* One year to two or three years.

These queries and answers are meant to cover the average case coming under treatment—that is, a case with disease of decided amount and decided activity. It will not be denied that the usual aim is to get patients out of bed and about as early as possible—that is, to establish "tolerance," so as to make way for others.

Out-Patient and Dispensary Treatment.

Here we have to deal with patients freshly diagnosed or freshly under observation, and patients who have regained their lost tolerance after a short period of hospital or sanatorium treatment.

Q. Have these patients active disease?—*A.* For the most part yes, some with "tolerance" (i.e., without fever), and others with decided fever and awaiting admission to a bed.

Q. Should these patients with active disease be walking about?—*A.* No! Those with tolerance are yet subjecting their disease areas to movement and congestion; those with fever are suffering, in addition, from unrestrained and harmful "focal reactions."

Q. Do these patients walk about—for the most part without restriction?—*A.* It will not be denied that they do; it is not, the writer thinks, always ascertained beforehand whether a case marked for admission has fever, nor are these cases often sent to bed until admission as they undoubtedly should be. If bed were recognised by the profession generally as the routine treatment of all cases freshly diagnosed it would be more easy to force it successfully upon the unwilling hospital or dispensary out-patient.

At this point it is due to admit the argument that there may be robust patients with slight lesions showing a tendency to healing in whom "febrile" and "focal" reactions and some grade of movement may be permitted without harm. Nevertheless, it is probable that we take this too much for granted in this country. It is undoubted that the general health and immunity of such a patient may improve and that his lesion heal, but it may well be that it does so with a fibrosis more widespread than was necessary (see on). With healing lesions of wide extent this may lead to permanent disability. Moreover, who is to exclude the presence of caseous areas whose softening and discharge may still further hinder recovery? But the writer does not wish to revive here the "rest versus exercise" controversy—his argument is directed towards severe or decided tuberculous disease among the hospital class.

Where the Present System Fails.

Obviously it fails in this—that early cases are often allowed to do themselves irreparable harm before admission to hospital or sanatorium; and that all through treatment cases of active disease are about and exercising. In this connexion it may be interesting to call to mind our knowledge of the means whereby the body fights tuberculosis. There are, we know, "immune responses" to "antigen" (auto-tuberculin) whereby antibody is formed and the bacillus gradually overcome. These "immune responses" are interrupted where the body is overcome by toxæmia (uncontrolled auto-inoculation and fever), but begin again when rest reduces the blood-flow to the lungs, and less toxin is washed out. As disease becomes less active and begins to heal toxins are diminished, but long before activity has gone the body will learn to establish "tolerance" to the toxins (? antituberculin). Hence patients can and do go about with unhealed and still active disease though with little or slight symptoms, and here is the danger. Not only are they running constant risk of further activity brought about by some excessive auto-inoculation (over exercising, &c.) and the neglect of this when it comes, but also the resolution of their disease is almost certainly delayed and rendered less complete. It has been demonstrated that a chemical irritant injected into the lung excites zones of inflammation varying with the concentration of the irritant—a central necrosis, next a fibrinous layer, then serous inflammation, and lastly a zone of proliferation of fibrous tissue. A similar process occurs in tuberculosis. When the lung is kept at the maximum of rest a zone of fibrous tissue will be developed at the line of "optimum irritation" and good encapsulation ensue. If movement and blood-flushing is allowed (under exercise) there will be no fixed optimum, and a wider diffusion of less well-developed fibrous tissue will result in place of an effective limiting capsule. Moreover, in areas where exudative or broncho-pneumonic processes occur and caseation ensues this is likely to soften and discharge itself under movement and increased blood-supply, as can be readily demonstrated with caseous cervical glands. In the neck this may accelerate healing, but in the lung this process leaves behind a cavity which the tissues, extended under a high negative pressure, cannot again close. Thus is exercise during activity of disease responsible for its delayed healing and spread.

The Corollary.

So much for facts which will not be seriously disputed by tuberculosis workers, albeit here rather dogmatically stated for the sake of brevity. Where, we must ask, do they lead? Obviously to this:—

1. That bed is indicated as soon as ever tuberculosis is suspected or detected, and that, in the hospital class, it should be continued, for safety, until disease is practically arrested. It will be recognised that we are here playing for safety—we have to choose, not between rest and therapeutic exercise, but between rest and *uncontrolled* exercise! It has been remarked that in the treatment of tuberculosis exercise is as valuable as rest *but far more dangerous*—among the ignorant working class it is disastrous!—rest is the only safety!

2. That, since pulmonary tuberculosis is a disease which takes a year or longer to cure (the time would be greatly shortened if cases took to bed at the first symptoms), it is obvious that we cannot give bed-rest during the whole stage of activity in institutions, and that *the patient's own bed, moved into the open or near a window, is the only place where immediate and prolonged rest treatment can be carried out.* This, in the writer's opinion, is the only logical solution of the treatment of tuberculosis in the working class, and its principles, at least, might well be also seriously considered and taken to heart by those who treat patients of a class who can afford to do the best for themselves.

Bed-Rest for the Tuberculous Poor—the "Class Method."

Fortunately the treatment of the tuberculous poor in their own beds has been already tried, and tried with success. Pratt, of Boston, described his "class method" of treatment so long ago as 1908 in the *British Medical Journal.* The patients lie out on balconies, roofs, or in yards, but a bed at the open window with the sashes removed would, the writer thinks, serve the purpose sufficiently well. Frequent visits are made by a special "visitor" (who would best be a nurse as far as provision could be made) and a record is kept of each case. The patient is recumbent or semi-recumbent and is advised to lie mostly on the diseased side under which a small firm pillow is placed. Visitors, excitement, and talking are avoided as far as may be. When they are judged fit for it patients attend once weekly at the medical centre to be weighed, and to have pulse and temperature recorded. The names of those who have gained most weight, and of those who have spent most time in the open air are chalked up on a blackboard. The patients chat among themselves, are given a few minutes' "talk" by the doctor, and then disperse. Their chests are examined monthly. Membership of each "class" is limited to 25, and in this is said to lie the secret of success, in that they become keen to compete with one another in the battle for health.

Adami has noted that in Montreal, where the method is being tried, the patients gained twice as much weight as did patients in a sanatorium, run on similar lines as to rest, 70 miles outside the city. This he ascribed to psychological causes, among which the "home" factor was considered important. The average bed-rest among Pratt's cases was four months, of graduated exercise combined with bed-rest four to seven months, and the whole treatment ran up to a year and in some cases longer. The moral suasion which will carry patients through this prolonged régime must be based on the tone of the "class" of 25 members, derived largely from the character and convictions of their doctor, on the effects of competition, and on the choice of the "visitor." There will be, under this and all systems and in every walk of life, patients whose characters lack the grit necessary for recovery from tuberculosis, and they must go under as now.

Pratt's intensive bed-rest system has enrolled in its favour many good American phthisiologists, among whom Bushnell, Kinghorn, and Schaefer may be mentioned, and the following figures of recovery are given for comparison with those for "graduated labour." I have here placed beside them also those of the King Edward VII. Sanatorium, Midhurst, for 1917:—

Years after discharge.	Frimley cases (large numbers) at work.	Midhurst (all cases T.B. +), "well" or "alive."	Pratt's unselected cases, all T.B. + (191 altogether), at work.
	Per cent.	Per cent.	Per cent.
1	61	69	95
2	50	61	92
3	46	50	87
4	44	47	76
5	39	39	71
6	42	38	69
7	23	38	70
8	—	33	70
9	—	38	64
10	—	34·7	50

The figures for Pratt's bed-rest system are too striking to be accepted without further careful evidence, and his material is certainly over-small for statistical valuation. If further experience proves them to be anywhere near the truth there is little doubt where the secret of this success lies—namely, in the institution of *rest at the outset.* Under our present system the patient is allowed to muddle himself into severe and often ineradicable disease before any real treatment is started. If, as soon as disease was suspected or diagnosed, the patient went straight home to bed and remained there, there would undoubtedly be many more real recoveries than occur at present.

But whatever the value of these figures may be we have here, at any rate, a system of treatment based on safe lines and sound principles, which has worked in practice, has elicited the enthusiastic approval of men on the spot, and seems capable of infinite extension. It amounts to a modified dispensary system and would, no doubt, entail careful organisation, but it demands little or no institutional treatment, and should hence prove less costly, on the whole, than our present schemes. Indeed, Adami, working it out on his Montreal experience, suggests that 8 to 11 months of this treatment would cost about £16, as compared with £25 for 10 weeks of treatment under present methods—with results which we all deplore! (The former figure, however, seems to ignore the cost of maintenance, which here falls on the patient, while the latter presumably includes it.) Tents, "balconies," blankets, and reclining chairs were furnished free of cost (presumably lent) to Pratt's Boston patients.

In this country, where institutions already exist, it might be used as a supplement to these. Especially "bed-rest" at home could be arranged and supervised so soon as the disease is first suspected or detected, and could be carried on some months,—four, six, or eight—before the patient's admission to hospital or sanatorium. These institutions could carry out, as now, that most needful business the graduated return of the patient to ordinary activities, but would then be doing so at the right moment—namely, after disease had been given time for quiescence, not, as now, when disease is still of decided activity. If all cases could start with a routine of four to six months' bed, under fresh-air conditions, disease would tend to be arrested at earlier stages, and after-results would surely be better than at the present time. There would, of course, still be cases caught too late, but there would be fewer of them—there would also be certain cases whose disease spreads in spite of all we can do to arrest it—there might also be cases which needed less than the care spent on them. The routine would be duly modified to meet these needs.

Being built up on the "expanding bookcase" principle, each "class" being a complete unit, the "class method" should be neither difficult nor expensive to handle, can be tested on a small scale, and can be carried out equally well in small or in crowded areas. If medical opinion were roused to adopt such a method it might become the useful practice of doctors to send to bed all patients suspected of pulmonary tuberculosis pending its definite diagnosis (and, incidentally, to start a "resting temperature" chart!). This would be a great step forward in the interests of all classes! Having long watched, as have so many others, with a heavy heart, the disappointing results of our present system, the writer would put in this plea for a change, based on the view that rest is the only safe treatment for the tuberculous poor so long as disease remains active or incompletely arrested.

THE CHAULMOOGRA PLANT IN LEPROSY: AN ANCIENT REMEDY.

To the Editor of THE LANCET.

SIR.—In your issue of Jan. 13th I read under this heading an ancient story by Major-General Sir Patrick Hehir on the efficiency in leprosy of the kalaw tree, from which chaulmoogra oil is obtained. The story narrates its use by Rama, a king of Benares, who was afflicted with leprosy, and who also cured Princess Piya of the same disease by these means. Later on she is said to have married him, and to have presented him with twin sons on 16 occasions. I do not know where he got hold of this ridiculous story. Rama never went into exile for leprosy, and the successive story has no foundation.

Sir Leonard Rogers has carried out recent experiments in chaulmoogra oil, but it is right to remember that long before his work the late Dr. Bhau Daji, of Bombay, a literary and talented university medical man, and Dr. Anna Moreshwar Kunte, demonstrator of anatomy in the Grant Medical College, Bombay, were using chaulmoogra oil in leprosy both externally and internally, with good results (vide Bombay Royal Asiatic Society's records, Researches by Dr. Bhau Daji). A description of the drug is in the Pharmacographia Indica, by Dr. W. Dymock (1890, i., 142), and gives a history of chaulmoogra oil as used in leprosy up to the indicated date. An account of the chemical constitution of chaulmoogra oil can be found in the Transactions of the Chemical Society, 1904–05.

I am, Sir, yours faithfully,
G. C. KUSUMBEKER, M.R.C.S., L.R.C.P. Lond.
Torrington-square, London, W.C., Jan. 24th, 1923.

MEDICAL STUDY IN GERMANY.

To the Editor of THE LANCET.

SIR,—I should like to endorse your Berlin correspondent's article on the above subject in THE LANCET, of Jan. 20th. I spent two months in Berlin recently and visited several teaching centres and came into contact with many medical students. The teaching of surgery and midwifery in particular seemed to me very extraordinary after being accustomed to having beds allotted to one in the wards and being able to follow up one's cases; and in the case of midwifery to conduct labours on one's own responsibility in the hospital extern maternity department. The surgery lecture-demonstrations I attended were held in a semi-circular theatre with about 200 numbered tip-up seats. Down below a small army of assistants, subassistants, and assistant subassistants would make their appearance, followed by a patient in bed; and then the professor. Two or three students would descend to the "arena" and be allowed to examine the case—generally in a slip-shod manner. After the professor had made a diagnosis and outlined the treatment, the case would retire and another enter. The treatment depended largely on what could be obtained—many lines of treatment were taboo on account of the expense; iodine in particular was relatively extremely expensive. Many of the students I met had only examined cases for two or three mornings in two terms. In the midwifery section the women were brought into a similar theatre on couches, generally in the lithotomy position with handkerchiefs over their faces. A retroverted uterus would be corrected, or a prolapsed cord replaced and the patient disappear, never to be seen again by the students. They were fortunate if they could do a few vaginal examinations during their course. There are university polyclinics where students can attend if they wish, but even then they only see a few patients and the number of students makes it impossible for them all to attend these clinics.

The students themselves were a very mixed lot—I should think not more than 60 per cent. were Germans. There were many Czecho-Slovakians, the rate of exchange being in their favour and the language presenting no difficulty. Also I was struck by the number of oriental students, especially Japanese. The German medical student class are having a great struggle to exist; most of them are working as well as studying (as, of course, many French students have to do also). One man nearing his final examination was attending his lectures in the mornings, assisting a private doctor in the afternoons, and working as an English- and French-speaking telephone operator for the Inter-Allied Commission from 9 P.M. to 9 A.M. Another man was a cinema pianist, and yet another was a lamplighter. The lack of clinical experience and the conditions under which these people learn, makes one think that there is probably some truth in the term "Arm-chair Professors" that has been levelled at some medical scientists.—I am, Sir, yours faithfully,

J. NORMAN WHEATLEY.
London Hospital, E., Jan. 22nd, 1923.

ARTICLES SENT BY POST FOR MEDICAL EXAMINATION OR ANALYSIS.

THE Postmaster-General has called our attention to the fact that pathological specimens are frequently sent by post, by members of the medical profession and other persons, in packets which are not made up in accordance with the regulations published at pages 22–23 of the Post Office Guide. Apart from their liability to cause damage to other packets conveyed in the same mails and to injure officers of the post office, packets of the kind found not properly packed are regarded as prohibited articles and are destroyed.

The following official leaflet summarises the regulations:—

DELETERIOUS LIQUIDS OR SUBSTANCES.

Articles sent for Medical Examination or Analysis.

Deleterious liquids or substances, though otherwise prohibited from transmission by post, may be sent for medical examination or analysis to a recognised Medical Laboratory or Institute, whether or not belonging to a public health authority, or to a qualified Medical Practitioner or Veterinary Surgeon within the United Kingdom, by *Letter Post, and on no account by Parcel Post*, under the following conditions:—

Any such liquid or substance must be enclosed in a receptacle, hermetically sealed or otherwise securely closed, which receptacle must itself be placed in a strong wooden, leather, or metal case in such a way that it cannot shift about, and with a sufficient quantity of some absorbent material (such as saw-dust or cotton-wool) so packed about the receptacle as absolutely to prevent any possible leakage from the package in the event of damage to the receptacle. The packet so made up must be conspicuously marked "Fragile with care," and bear the words "Pathological Specimen."

Any packet of the kind found in the parcel post, or found in the letter post not packed and marked as directed, will be at once stopped and destroyed with all its wrappings and enclosures. Further, any person who sends by post a deleterious liquid or substance for medical examination or analysis otherwise than as provided by these regulations is liable to prosecution.

If receptacles are supplied by a Laboratory or Institute, they should be submitted to the Secretary, General Post Office, in order to ascertain whether they are regarded as complying with the regulations.

THE BOSTON CITY HOSPITAL.

THE report of this institution which, with its various annexes and convalescent home, contains 1207 beds, has just been issued for the fifty-eighth year of its existence. It is an elaborate analytical document of 118 pages, and is a record of excellent work. To the hospital proper there were admitted during the year ending Jan. 31st, 1922, 17,576 patients, the number of patients treated in the out-patient department during the same period being 32,377. The cost per day for each ward patient was $3·03; for each patient at the convalescent home $2·45. In the report of the pathological department it is sadly pointed out that inasmuch as there are no promising financial prospects for pathology as a life work, the department is used as a stepping-stone to something more remunerative. The laboratory is trying the experiment of having as assistant a medically trained woman who desires to make pathology her profession. A thyroid clinic has been established for the purpose of aiding in the diagnosis and treatment of possible thyroid disorders, and during the year 496 basal metabolism tests have been done on 322 cases. As a result of prohibition new and strange concoctions are being drunk by those addicted to the use of alcohol, and the poisonous nature of these beverages has made it necessary to admit every case of addiction, thus adding greatly to the burdens of the institution.

INDEX TO "THE LANCET," VOL. II., 1922.

THE Index and Title-page to Vol. II., 1922, which was completed with the issue of Dec. 30th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2.

Hunterian Lecture

ON THE

RELATION OF

DISEASE OF THE GALL-BLADDER

TO THE SECRETORY FUNCTION OF THE STOMACH AND PANCREAS.

Delivered at the Royal College of Surgeons of England on Feb. 5th, 1923,

By H. ERNEST GRIFFITHS, M.S. Lond.,
F.R.C.S. Eng.,

HUNTERIAN PROFESSOR, ROYAL COLLEGE OF SURGEONS OF ENGLAND; DEMONSTRATOR OF ANATOMY, ST. BARTHOLOMEW'S HOSPITAL MEDICAL SCHOOL; SURGEON TO THE ALBERT DOCK HOSPITAL; REGISTRAR TO THE ALL SAINTS HOSPITAL.

Introduction.

Disease of the gall-bladder has long been recognised as a cause of digestive disturbance. It will be my endeavour first to trace the anatomical and physiological relations of the gall-bladder to the stomach and pancreas, paying particular attention to the control exercised by the sympathetic filaments derived from the ninth thoracic segment of the cord and the vagus; then to analyse some symptoms and signs of gall-bladder disease, showing how many of them are dependent on disturbance of gastric and pancreatic functions; finally to enumerate a few tests which may be used to determine error in the secretion of the stomach and pancreas.

Anatomical Relationship of Gall-Bladder.

The close anatomical relationship of the pylorus, the first part of the duodenum, and the head of the pancreas with the gall-bladder need not be emphasised here. There are, however, a few points concerning their peritoneal connexion, nerve-supply, and lymph drainage which must be carefully considered. The fundus of the gall-bladder is surrounded by parietal peritoneum. The body, however, is only covered on its sides and inferior surface, its upper surface being bare and approximated to the right lobe of the liver. Passing from the neck of the gall-bladder downwards to the first part of the duodenum, and sometimes crossing this to reach the transverse colon, is found a crescentic fold of the peritoneum with a free anterior edge. This has been variously called the cysto-colic, hepato-colic, and cysto-duodenal ligament. Addison found it present in 33 per cent. of cases. In 100 consecutive cases which I have examined at operation, in the post-mortem room or dissecting room, the fold was present in 52, absent in 24, and in the remaining 24 there were so many adhesions around the gall-bladder that it was impossible to say whether the fold were originally present or not. The cysto-duodenal fold is a remnant of the anterior part of the ventral mesogastrium. Contraction of this fold, due to inflammatory changes in the gall-bladder, tends to cause constriction of the duodenum and may be one of the factors concerned in the causation of the regurgitation test-meals commonly found in gall-stone cases. Bricon wrote that the cysto-duodenal fold functioned as a safety-valve in gall-stones by contracting during inflammation and approximating the gall-bladder to the anterior surface of the duodenum, so that the stones might ulcerate through the walls of the viscus into the gut and a spontaneous cure result. In one case I have seen complete obstruction to the duodenum by the cysto-colic fold. The case was diagnosed as carcinoma of the pylorus, and the true condition was found at operation.

Lymphatics.

The efferent lymphatic vessels of the gall-bladder pass in the main to a lymphatic gland situated at the junction of the cystic duct with the neck of the gall-bladder, and from there downwards in the gastro-hepatic omentum in relation to the common bile-duct; several lymph-nodes which occasionally attain the size of glands interrupt their course. The relationship to the common bile-duct is maintained as that structure passes behind the first part of the duodenum to become embedded in the posterior surface of the head of the pancreas. Here they inosculate freely with the lymph vessels of the pancreas and duodenum, and share with them the retro-pancreatic lymph glands. Although the flow of lymph from the gall-bladder in normal conditions passes directly to the receptaculum chyli via the retro-pancreatic and cœliac groups of lymph glands, in inflammatory conditions, where some of the channels become occluded, this lymph finds its way into the pancreatic plexus and infection is thus communicated directly to the pancreas.

Nerve-supply.

The nerve-supply of the gall-bladder is derived from the hepatic plexus, the filaments being conducted to their destination along the cystic artery and its branches. The hepatic plexus is an offshoot from the cœliac plexus, which is derived from the fifth to the tenth thoracic nerves via the great and small splanchnics and the right vagus. In the small omentum the hepatic plexus is joined by the branches from the left vagus and also from the diaphragmatic ganglion which marks the junction of the diaphragmatic plexus with the right phrenic nerve. Thus, from a purely anatomical study it might be assumed that the gall-bladder received its nerve-supply from the fifth to the tenth thoracic nerves, both vagi, and the right phrenic. The vagi are undoubtedly the motor nerves to the viscus. There is considerable difference of opinion as to whether the liver, gall-bladder, and biliary passages are endowed with sensory nerve filaments. At one time it was almost universally accepted that the right phrenic nerve supplied the liver and the gall-bladder with sensation, but many anatomists now consider that all sensation of the gall-bladder is due to interference with its peritoneal covering. According to K. G. Lennander, the parietal peritoneum is intensely sensitive to pain, but not to pressure, heat and cold, and this sensibility is increased by inflammation. He states that the visceral peritoneum and abdominal organs are entirely devoid of any sense of pain when inflamed, and that all pain arising from disturbances within the abdominal cavity is caused by irritation through the spread of inflammation to the abdominal walls or pressure exerted upon those parts inervated by the cerebro-spinal system, and that those parts supplied by the vagus and sympathetic nerves only have no afferent fibres for the transmission of painful impulses.

In operations performed on the upper abdomen under local anæsthesia stimulation of the gall-bladder does not produce pain, but this in itself is not a proof of the absence of sensory fibres. Kast and Meltzer, of the Rockefeller Institute, showed that cocaine acts centrally as well as peripherally. When an animal is operated upon under local anæsthesia the abdominal viscera appear to be insensitive to painful stimuli. If, however, the abdomen is opened without anæsthetic, stimulation of any organ causes pain which may be abolished by the injection of cocaine into the limb of the animal. Sensation is similarly lost after exposure of the viscera to the atmosphere. This accounts for the well-known surgical phenomenon that a colostomy may be opened without anæsthetic after the initial operation. All surgeons know that a colostomy is not invariably insensitive. Kast and Meltzer summed up their work by stating that "all experiments lead up to the one unmistakable result which can be stated in a few words: the normal gastro-intestinal canal possesses a sensation of pain." In support of the view that the phrenic nerve supplies sensory fibres to the gall-bladder, cases of gall-stones are quoted in which pain was referred along the phrenic nerve to other branches of the cervical plexus supplying the skin in the region of the point of the shoulder and the axilla. In the series of cases which I have examined this referred pain has been a rare symptom, always associated with spread of inflammation to the parietal peritoneum in relation to the diaphragm, thus directly affecting the twigs of the phrenic nerve which pierce that muscle. Working purely on an anatomical basis, Ramstrom was unable to demonstrate any filaments of the phrenic or intercostal nerves entering the liver.

In inflammatory conditions of the gall-bladder there is frequently an area of hyperæsthesia which follows closely the distribution of the ninth right intercostal nerve. In two cases I have seen an attack of herpes zoster affecting the area of skin supplied by this nerve following an attack of acute cholecystitis. Frequently a zone of hyperæsthesia is found below the angle of the right scapula over an area of skin which is supplied by the posterior branch of the ninth intercostal nerve. To sum up: The vagus is the motor and secretory nerve to the gall-bladder and bile passage, and is inhibitory to the sphincter of the ampulla of Vater. The sympathetic deriving its fibres from the ninth right intercostal segment is the sensory nerve to the gall-bladder; it is inhibitory to the muscular wall, but supplies the motor filaments to Oddi's sphincter. Thus stimulation of the vagus causes emptying of the gall-bladder through a relaxed sphincter, and stimulation of the sympathetic causes closure of the sphincter and filling of the lax-walled gall-bladder with bile. The vagus in the stomach is, again, the motor and secretory nerve and is inhibitory to the pyloric sphincter. The sympathetic derived from the fifth, sixth, seventh, eighth, and ninth thoracic segments is inhibitory to the muscle in general, but motor to the pyloric sphincter. The ninth intercostal segment is mainly responsible for the contraction of the pylorus. The pancreas derives its nerve-supply from both sympathetic and vagus. Stimulation of the vagus causes profuse, thin secretion from the pancreas, whereas stimulation of the sympathetic is followed by a small but thick secretion. My investigations upon the nerve-supply of the pancreas are not yet complete, but so far they seem to point to the fact that the sympathetic filaments are mainly derived from the ninth thoracic segment.

Physiological Relationships of the Gall-Bladder.

It is now necessary briefly to review the normal physiological relationship between the stomach, pancreas, and gall-bladder. Appetite and the ingestion of food into the stomach are the signals for the secretion of acid gastric juice; the pyloric canal is firmly closed, and the peristaltic waves of the stomach churn up the food and impel it against the barrier of the pyloric sphincter. As the food gets broken up the stomach contents become more acid, the sphincter relaxes, and a little chyme is squirted into the duodenum, where its acidity causes immediate reflex closure of the pylorus. This process is repeated until the stomach is emptied. While this process is going on secretin is produced, which stimulates the pancreas and liver to the increased production of their digestive ferments. Rhythmical contractions of the gall-bladder also occur, and its store of concentrated bile is added to that produced by the liver. The presence of the alkaline juices in the duodenum rapidly neutralise acid chyme escaping from the stomach, and themselves tend to produce a reflex relaxation of the pyloric sphincter. In the later stages of gastric digestion the movements of the stomach become less violent, and the pressure within is considerably diminished. At the same time the alkalinity of the duodenum rises, with resultant reflex inhibition of the sphincter, and thus a small amount of regurgitation occurs periodically from the duodenum to the stomach.

The liver and the pancreas are both stimulated by the same hormone secretin, and their outflowings pass to the duodenum through a common opening. It is evident, therefore, that there must be a close relationship between the bile and pancreatic juice. Chemical investigations have proved that the digestive activity of pancreatic juice is increased twofold by an adequate quantity of bile. One phase of my work has been to study the effect on digestion of the elimination of the gall-bladder by disease. In all diseased conditions of the gall-bladder its function as a reservoir of bile is temporarily or permanently abolished. The majority of cases which I have studied have been inflammatory, generally complicated by the presence of gall-stones. It has long been known that in such cases the little muscular tissue of the gall-bladder is gradually replaced by fibrous tissue, and its elasticity is lost. On this pathological fact Courvoisier based the interpretation of his law. Studying these cases from the physiological point of view, and for the moment ignoring the pathological aspect, a condition is produced equal to extirpation of the gall-bladder from the biliary circulation. Considering this from a purely theoretical point of view, it would be expected that the bile from the liver would pass in a steady stream into the duodenum with no reserve collection for use when most needed for digestion. The bile entering the duodenum when the stomach is at rest would produce a relative increased alkalinity on the distal side of the pylorus resulting in inhibition of the sphincter and consequent regurgitation into the stomach. Small doses of alkali injected into the stomach would stimulate the secretion and produce a condition of hyper-acidity, which, however, would tend to be neutralised by the alkaline causative agent. The effect of this constant stimulation of the stomach with neutralisation of its contents produces a condition of atonia of the walls of the viscus, but also hypertrophy of the pyloric sphincter from its constant exercise. In the normal process of digestion bile does not start to flow freely into the duodenum until the acid chyme has entered. Where bile is passing constantly into the duodenum in the early stages of digestion, however, it still tends to regurgitate into the stomach, neutralising the gastric juice and interfering with the process of gastric digestion.

So much bile having been wasted between meals, there is an insufficient store forthcoming for the process of digestion. This defect makes itself most felt in its effect on the pancreatic juice, the activity of whose ferments is very much diminished by the absence of bile. The fat-splitting ferments in particular are affected, and it would, therefore, be expected that in patients suffering from this condition there would be inability to digest fatty foods. The effect is also marked on the protein-splitting ferments, and the incomplete digestion of protein leads to increase in intestinal decomposition and toxæmia, with resulting indicanurea. It must be remembered that nature generally attempts to make some compensation for loss sustained to the body. When the normal gall-bladder is removed, the common bile-duct endeavours to take its place as a reservoir by dilation. The amount of the bile held in this way is inconsiderable, unless there is some pathological obstruction to its outflow, and its composition remains the same as when it was secreted by the liver.

Inflammation.

Inflammatory lesions of the gall-bladder may produce disturbances in the neighbouring organs in four ways: (1) By destroying its physiological function, as already described; (2) by reflex action; (3) by direct spread of infection; (4) by toxic effect. Inflammation of the gall-bladder is, in the majority of cases, produced by infection with the *Bacillus coli communis*. In a few cases other organisms of the coliform group are found, and more rarely streptococci. It is beyond the scope of this lecture to discuss in detail the route by which the gall-bladder becomes infected; in my opinion, however, it is generally infected by organisms in process of elimination from the portal system by the liver.

Infection may be carried from the gall-bladder to the pancreas by four routes: (1) By the common bile-duct to the ampulla of Vater, then by regurgitation along the main pancreatic duct; (2) by the lymphatic stream already described; (3) by the blood-stream; (4) by direct infection in those cases where the gall-bladder becomes adherent to the duodenum and lies in close proximity to the head of the pancreas. The two latter routes are of great rarity and will not now be discussed.

Bile in the common bile-duct normally flows at a pressure equal to that of the juice in the pancreatic duct, about 40 mm. of water, so that there is no tendency for regurgitation of bile from the ampulla of Vater along the pancreatic duct. If the pressure tends to rise in the common bile-duct, the gall-bladder, dilating, acts as a safety-valve and reduces the tension. When, however, the gall-bladder contracts in the process of digestion, there is inhibition of Oddi's sphincter, and a free flow of bile into the duodenum results. In certain conditions obstruction to the outflow of bile occurs at the duodenal orifice of the common bile-duct. In these cases there is a tendency for regurgitation of bile towards the pancreas. One cause of obstruction is a gall-stone impacted in the ampulla of Vater. In many cases the impacted stone not only prevents bile in any quantity in passing into the duodenum, but is so situated as to prevent its entrance into the pancreatic duct.

Another common cause of obstruction is carcinoma of the head of the pancreas, which involves not only the terminal part of the common bile-duct but also the pancreatic duct.

Sclerosing pancreatitis also has the effect of inhibiting the flow of bile into the duodenum, but it nearly always does so by pressure on the common bile-duct proximal to the ampulla; at this stage of the disease, therefore, regurgitation of bile is unlikely to take place, although its previous occurrence may have been one of the causes of the sclerosing pancreatitis.

Finally we must consider Oddi's sphincter itself. The occurrence of spasm of this muscle may cause a transient flow of bile into the pancreas in cases where the gall-bladder is already diseased, and cannot act as a safety-valve. The bile may penetrate only a short way along the pancreatic duct and then, with the relaxation of Oddi's sphincter, be washed back into the duodenum by the pancreatic juice; but its stay in the pancreas has been long enough to occasion infection without producing such serious changes as would have occurred had the obstruction in the ampulla of Vater been permanent.

Catarrhal jaundice should be mentioned here as a possible cause of regurgitation of bile, but in the majority of cases the swelling of the mucous membrane of the bile-duct extends above the ampulla of Vater and causes obstruction at a higher level.

Changes in the Pancreas due to Infection from the Gall-Bladder.

Such changes are :—

(1) Catarrhal pancreatitis due to direct inoculation of the mucous membrane of the pancreatic duct with infected bile, generally occurring as the result of a spasm of Oddi's sphincter. The temporary arrest of the secretion of pancreatic juice into the intestinal tract produces considerable disturbance in the process of digestion, particularly of fats, and results in one of those well-known attacks of diarrhœa which are occasional features in some cases of gall-stones. Vomiting may be a serious symptom in these cases, and is proportionate to the degree of infection of the pancreas.

(2) Chronic parenchymatous pancreatitis, which can be detected macroscopically or microscopically in all cases of long-standing infection of the gall-bladder. It is due to infection by organisms carried from the gall-bladder to the pancreas in the lymphatic stream. In the majority of cases it produces few gross symptoms, because the islands of Langerhans are only slightly involved, and because the alveoli of the major part of the body and the tail of the gland generally escape. In a few cases, however, sclerosis of the head of the pancreas is sufficient to cause obstruction to the pancreatic and common bile-ducts. The condition may then easily be mistaken for carcinoma of the head of the pancreas. In the larger group of cases careful pathological examination will generally reveal evidence of disturbance of both the internal and external secretions of the pancreas. This subject will be referred to later.

(3) Acute pancreatitis of the hæmorrhagic, suppurative, and gangrenous varieties is, in my opinion, almost always due to infection from the gall-bladder. It may be impossible to determine the route of infection at operation or autopsy, owing to the extensive destruction of pancreatic tissue. In some cases there is very definite evidence of regurgitation, in other cases there is none, and it must be presumed that the infection spreads via the lymphatics.

The Common Bile-Duct and the Sphincter of the Ampulla of Vater.

I should like to consider for a few moments the changes that may occur in the common bile-duct and the sphincter of the ampulla of Vater (Oddi's) in so far as they are concerned with the condition already described. I have already referred to catarrhal changes in the mucous membrane, and shall now deal only with the fibrous and muscular coats. The passage of irritant fluid, such as infected bile, always tends to produce increased muscular activity in an endeavour to expel it. The walls of the common bile-duct contain very little muscular tissue, but what is there contracts in peristaltic waves and, at the same time, reflexly, causes inhibition of Oddi's sphincter. At times it appears that the peristaltic action loses its rhythm, and the most marked result is a temporary spasm of the ampulla of Vater. The muscle in this region is so much greater than that in the common bile-duct that where the latter is diseased it becomes a law unto itself, and if for any reason there occurs contraction of the sphincter, independent of the muscle impulses passing down the bile-passages, the spasm produced is sufficiently strong to ignore the natural stimuli. It is found that spasm of the sphincter of the pylorus is associated with spasm of Oddi's muscle, and if a relationship can be found between pyloric spasm and disease of the gall-bladder, another very definite reason may be deduced for the temporary obstruction to the flow of bile into the duodenum and its temporary regurgitation along the pancreatic duct. The infected bile entering the duodenum sets up a mild duodenitis which in itself is one of the most frequent sources of pyloro-spasm.

THE REFLEX NERVOUS ARC.

Irritation of the mucous membrane of the gall-bladder causes a reflex irritability of the vagus which is most marked by its action in the stomach, where an increase in the amount and acidity of the gastric juice is produced, associated with relaxation of the pylorus and regurgitation from the duodenum. Whereas in the majority of cases the vagus reflex is the more marked, in others the sympathetic reflex is more evident. In this type of case the inflammation is generally less chronic. As would be expected, it is shown by increased action of that portion of the sympathetic derived from the ninth thoracic nerve. There is spasm of the ampulla of Vater and relaxation of the gall-bladder walls with consequent dilation of the viscus; in the stomach there is spasm of the pylorus, but as the ninth thoracic segment supplies only the pylorus there is no sympathetic effect on the remainder of the stomach, and the vagus reflex remains unchecked, causing hyperchlorhydria and contraction of the organ. The first and second parts of the duodenum are dilated and the pancreatic secretion is concentrated but small. This condition is clinically known as pyloro-spasm, and although in the majority of cases the irritating focus is in the gall-bladder it may occur anywhere in that portion of the digestive tract where the terminal filaments of the sympathetic derived from the ninth thoracic segment are found—namely, gall-bladder, bile-ducts, pylorus, the first and second parts of the duodenum, and the pancreas.

I wish now to dwell for some time on the evidence of gastric and pancreatic disturbance which may be deduced from the history and clinical examination of patients suffering from gall-bladder disease. Here I shall take as a type cases of cholelithiasis associated with cholecystitis. From the patient's point of view, the most important symptom of the gall-stones is pain, which may be of three types: (1) biliary colic, (2) biliary ache, and (3) biliary dyspepsia.

Biliary Colic.—This is an agonising pain, starting in the right side of the abdomen. Usually, when it can be accurately located, at a point one-third of the way from the tip of the ninth right costal cartilage to the umbilicus, but the point of maximum intensity of the pain varies slightly in position, and may be found immediately below the xyphoid cartilage or deep behind the eighth or ninth right costal cartilage. The pain is seldom limited to this one spot; it is generally described as shooting through the "right shoulder." On careful questioning of the patient, the right shoulder is found to refer to the right inferior scapular region. Instead of passing to this region by the direct route, the pain is often stated to shoot round the chest on the right side, following the course of the ninth intercostal nerve. Less commonly pain is referred to the inferior angle of the left scapula; in these cases it appears to shoot through the thorax and never round the left side. Again, the pain may be felt behind the inferior angles of both scapulæ. The pain frequently radiates down the abdomen as far as the umbilicus and sometimes into the right loin. The distribution of referred pain on which most stress has been laid by the majority of authors is one radiating upwards from the right hypochondrium to the point of the shoulder and the axilla on the right side. When present this symptom is pathognomonic of a severe inflammatory lesion of the hepatic, biliary, or right diaphragmatic regions. This pain never occurs in gall-stone colic uncomplicated by acute or subacute cholecystitis. The onset of the colic is sudden, and its intensity rapidly increases to reach a maximum in a few minutes. The attack may last for half an hour or be prolonged for several hours, with short respites from the more severe pain. The colic ceases as abruptly as it commenced, but is always followed by a feeling of soreness underneath the right costal margin and in the region immediately below it. Usually the pain starts half an hour or more after a full meal, sometimes when the patient is in bed, and sometimes after he has been shaken by riding or motoring. Although in this lecture I do not propose to deal with the effect of stomach and pancreatic functions on the disease of the gall-bladder, it may be noted again that the digestion of food in the stomach and duodenum, through the production of secretin, stimulates the muscle of the gall-bladder, and the normal inhibition and contraction of the pyloric sphincter reflexly find their counterpart in the movements of the sphincter of the ampulla of Vater and the neck of the gall-bladder. In this way it will seem that the passage of a stone from the gall-bladder towards the duodenum is more likely to occur within the first two hours after a meal than at any other time. In long-standing cases, where the muscle of the gall-bladder has been replaced by fibrous tissue, there is no response to the stimuli of the stomach, and biliary colic becomes a rare symptom.

Biliary Ache.—Gall-stone pain is frequently of a dull, aching character, interspersed with periods of acute exacerbation. It is referred to the right subcostal region and the right lumbar region, the pain appearing to travel through the abdomen between these two areas. A constant and steady pain in the right lumbar region, which may extend to the left side of the spine, is often present. It seldom becomes acute, and is not, therefore, usually a primary source of complaint on the part of the patient, but a leading question will nearly always establish its presence. It generally becomes most evident as the more severe anterior abdominal pain is subsiding. The onset of biliary colic has been already described as dramatically sudden; the pain now under review has a more insidious beginning. There is a vague feeling of abdominal discomfort, gradually increasing until pain becomes definite and localised. The severity of the pain varies considerably; it may cause little inconvenience, or the patient may be prostrated. In this acute condition the pain differs from biliary colic in several essentials; it is not of a griping nature, but is rather burning and stabbing, whilst referred pain along the superficial cervical plexus is the rule rather than the exception. The pain is sustained, and when remission occurs it is gradual. Shivering almost invariably heralds an attack, and always occurs before the rise of temperature. Constitutional disturbance is marked in severe cases, the temperature rising to 103° F. or higher, and the pulse-rate increases to 120–140. Furred tongue, constipation, scanty urine, and vomiting testify to the degree of toxæmia. It is evident that biliary ache is due to infection of part or all of the extra hepatic biliary apparatus, and that the pain is the result of inflammation. It may be caused by irritation of the nerve endings of the mucous membrane by producing a catarrhal condition of the bile-ducts resulting in increased resistance to the flow of bile and consequent increased tension in the liver and gall-bladder. The referred pain to the neck and acromial region only occurs when the inflammatory changes have spread to the serous coverings of the gall-bladder and the peritoneum on the under surface of the diaphragm, thus involving terminal sensory filaments from the right phrenic nerve. The ache in the lumbar region is due to the spread of infection to the head of the pancreas, resulting in congestion of that organ. It might be expected that there should be some anterior pain felt just above the umbilicus to demonstrate the involvement of the pancreas, but clinically it is impossible to differentiate between this pain and that due to the involvement of the bile passages and the neighbouring peritoneum.

Biliary Dyspepsia.—The third type of pain, usually described by the patient as "indigestion," appears to have a definite relation to meals. There is a feeling of weight and fullness in the epigastrium, accompanied often by a dull aching in the left scapular region. Flatulence is constantly associated with these symptoms, and belching or vomiting gives considerable relief. This condition is usually most acute about half an hour after taking food, and lasts about two hours. Almost every patient who has biliary dyspepsia discovers, sooner or later, that the old household remedy of a glass of hot water will give relief. It has been claimed that the drinking of a glass of hot water before meals is a panacea for all digestive ills. It may now be stated, with a greater degree of certainty, that the drinking of a glass of hot water after meals in women is diagnostic of one of the most severe of digestive ills—gall-stones.

VOMITING.

Vomiting is one of the commonest symptoms of gall-stones, and occurs in 81 per cent. of my cases. It occurs in a variety of different forms; in biliary colic with impaction of the stone, generally in the cystic duct, the patient experiences an extreme degree of nausea associated with a feeling of goose-flesh, which is rapidly succeeded by cold, clammy sweating and severe vomiting. The patient is quite prostrated, and, according to Moynihan, with the general loss of muscular tone the stone, which is at the mouth of the cystic duct, falls back into the gall-bladder, and relief of symptoms is obtained. He describes one case in which on two occasions he was able to detect the gradual enlargement of the gall-bladder accompanying two severe attacks of biliary colic with nausea and vomiting. In this patient the obstruction of the cystic duct was due to kinking and not to a stone. I have met two such cases; in one the obstruction was due to a solitary gall-stone, and in the other to a shrapnel ball. The latter was a case of a young officer who was wounded in the right side of the chest, the missile passing through the pleural cavity, the diaphragm, the right lobe of the liver, and penetrating into the gall-bladder. X ray localisation suggested that the position of the foreign body was in the right lobe of the liver, but succeeding attacks of biliary colic, accompanied by deadly nausea and vomiting, with coincident enlargement of the gall-bladder, succeeded by prostration with abatement of the symptoms, indicated the presence of the foreign body in the gall-bladder. The diagnosis was confirmed at operation, the shrapnel ball was removed, and as there was no evidence of inflammatory change in the walls of the gall-bladder it was closed. The patient made an uninterrupted recovery.

The vomiting associated with biliary colic is in the main reflex. In the first stage contraction of the walls of the gall-bladder is associated with regurgitation of duodenal contents through the pylorus, and the patient experiences nausea, rapidly succeeded by a reflex spasm of the pylorus in response to the spasm of the sphincter of the neck of the gall-bladder or the ampulla of Vater; peristaltic waves of the stomach wall increase and violent vomiting results.

Biliary dyspepsia is accompanied by vomiting of a different kind, occurring after a full meal, and not, as a rule, accompanied by much nausea. It is generally small in quantity and of a watery regurgitant type. Occasionally it is copious, resulting in complete evacuation of the stomach, and affording the patient complete relief from pain without producing that degree of prostration which is a feature of vomiting associated with biliary colic. Vomiting in these cases is due to direct irritation of the mucous membrane, the stomach having been rendered hypersensitive by inflammatory changes consequent upon the regurgitation of duodenal contents and the increased acidity of gastric juice.

A third type of vomiting occurs in patients who have been jaundiced. Nausea is again a distinctive feature, but the amount of material expelled from the stomach is often small. This vomiting may occur after every meal or, as is more frequent, attacks of short duration occur at regular intervals coincident with the rise and fall of the pigmentary curve. Two factors operate in producing this condition: first, the gastric irritability already described in biliary dyspepsia, and secondly, the toxic effect of the circulating bile on the vomiting centre in the medulla, shown by the increase in vomiting found with the increase in jaundice. A fourth type of vomiting which occurs in gall-stone patients is periodic. It does not appear to be associated with any gross disturbance of the gall-bladder or bile passages, although it may follow an attack of cholecystitis. It is not associated with that degree of nausea found in the first and third types, but is always accompanied by mild diarrhœa, the stools being fatty and undigested, resembling somewhat those found in cœliac disease. The attack generally lasts for several days, in more severe cases extending into weeks. Wasting is a very marked feature in cases of long duration. The character of the stool, with the marked increase in undigested fat, is symptomatic of pancreatic insufficiency. Other evidence of pancreatic insufficiency, such as increased diastase content of the urine, indicanurea, positive Loewe's mydriasis test, and sometimes transient glycosuria, all tend to add weight to the diagnosis. It may safely be assumed that this type of vomiting is due to a type of pancreatitis which involves both the internal and external secretion. I have not had the opportunity of making a post mortem on such a case, but hazard the opinion that the condition is due to catarrhal pancreatitis, the result of periodic invasion of the gland by micro-organisms derived from the gall-bladder.

The next class of case with which I propose to deal is that arising from ulceration of gall-stones through the wall of the gall-bladder into the alimentary tract and causing intestinal obstruction. It is difficult to speak of the vomiting in this condition as a definite fifth type, because as the disease progresses the causes and character of the vomiting alter. In the typical case the gall-bladder becomes adherent to the duodenum. At the commencement of the ulcerative process severe nausea and vomiting set in, similar to those experienced with the impaction of a gall-stone in the cystic duct. As the stone emerges into the duodenum the vomiting becomes more persistent and regurgitant in character, and may be found to contain a small amount of blood. When the stone has left the gall-bladder and commenced its journey down the small intestine, there is a temporary abatement of symptoms until the stone becomes impacted in some part of the bowel. As a rule impaction occurs for a short interval at several points before the calculus is brought finally to rest about 18 inches proximal to the ileo-cæcal valve. During the temporary stoppages there is considerable intestinal colic, which may be accompanied by reflex vomiting without nausea. When finally the intestinal obstruction has become established, vomiting once more becomes persistent, at first consisting of unaltered stomach and duodenal contents, but later becoming fæculent. In rare cases where obstruction occurs after ulceration of the stone into the transverse colon, the initial vomiting is less severe and no blood is found in the vomit. On the other hand, streaks of bright blood may be found in contents of the lower bowel evacuated before the obstruction occurs.

Jaundice.—Jaundice, although one of the classical symptoms of gall-stones, only occurs in about 17 per cent. of all cases. The percentage of hospital cases who suffer from jaundice is much greater because, as a general rule, only those come up for treatment who have suffered from biliary colic, which itself occurs in only a minority of cases. Jaundice, associated with disease of the gall-bladder, is essentially of the obstructive type. Clinically, it may be intermittent, remittent, or progressive. The onset of intermittent jaundice is generally preceded by an attack of biliary colic a few hours before. In a typical case the patient complained that she had an attack of pain in the evening and the next morning her friends noticed her eyes were yellow. Early jaundice is difficult to recognise in artificial light, which probably accounts for the fact that the condition is nearly always first recognised in the morning. This type of jaundice lasts for only two or three days, and may cause the patient little inconvenience; in the majority of cases it is due to the temporary arrest of a gall-stone in the common bile-duct, and subsequent inflammation and swelling of the mucous membrane. The degree of infection is reflected by the rise in the evening temperature to 101° F., which nearly always accompanies the case of transient jaundice. In the remittent type of jaundice the onset is similar to the one already described, but may persist for weeks and even months, and is never of the same intensity during the whole of that period. As a rule the degree of jaundice varies fairly regularly every three to five days, getting gradually deeper and lighter but never disappearing. A simple test for determining slight variations in the degree of jaundice may be made by collecting a little blood in a capillary tube, allowing it to stand, and comparing the pigmented serum with that taken at some other time. The jaundice in this type of case is due to a stone in the ampulla of Vater, causing incomplete obstruction. The morning and evening variation is due to the greater amount of bile secreted by the liver during the day.

The onset of progressive jaundice is insidious, and seldom associated with biliary colic as in the two previous types. The degree of pigmentation increases from day to day, and although in the early stages of the disease, before obstruction to the outflow of bile is complete, there may be slight variation between morning and evening, this soon disappears. The temperature generally remains normal, the obstruction may be due to the stone in the cystic duct causing lateral pressure on the common bile-duct, adhesions, or, more commonly, changes in the pancreas. Sclerosing pancreatitis, already described, causes increased pressure on the buried portion of the common bile-duct. Other evidence of the disease of the pancreas is forthcoming in periodic attacks of vomiting, with marked wasting and the undigested fatty stools to which I have already alluded. I have not endeavoured to describe all the methods by which jaundice may occur in cases of disease of the gall-bladder, but only to emphasise the type in which it is definitely associated with the kind of pancreatic complication which is dependent upon cholecystitis.

Clinical Examination of the Patient.

On inspection of the abdomen it is unusual to observe anything, apart from occasional jaundice, indicative of gall-bladder disease or associated disturbance of its neighbouring organs. In the majority of cases the patient is well covered; rarely, a visible fullness to the left of the mid-line may indicate distension of the stomach. Rapid loss of weight, with attacks of diarrhœa and vomiting, is shown by the looseness of the skin. When in such cases the skin is dry and parchment-like, or even scaly, further examination always reveals definite pancreatic involvement.

Findings on Palpation.—In acute, and often in subacute, cholecystitis definite areas of superficial hyperæsthesia can be made out. This hyperæsthesia most commonly follows the course of the ninth intercostal nerve on the right side; it is also found in the distribution of the branches of the right cervical plexus. On two occasions I have observed superficial hyperæsthesia over the seventh and eighth intercostal nerves on the left side. In each the symptoms appeared after the acute stage of cholecystitis had subsided and gastric disturbance had become a prominent feature. On deep palpation the most constant sign of gall-bladder disease is tenderness below the tip of the ninth right costal cartilage. In chronic cases which are associated with biliary dyspepsia there is generally tenderness below the ensiform cartilage, which is more or less constant in all inflammatory lesions of the stomach. Sometimes after an attack of cholecystitis, when the gall-bladder tenderness is no longer diffused over the upper abdomen but is limited to Murphy's sign, pain may be elicited by pressure above the umbilicus. When present, this points to subacute inflammation of the proximal portion of the head of the pancreas. Boas first described an area of tenderness on deep pressure extending for 3½ inches to the right of the spinal column on the level of the eleventh thoracic to the first lumbar spines. His explanation was that the tenderness was in relation to the posterior surface of the liver. The cases that I have examined in which there is tenderness in the loin fall definitely into two classes—those where a point of maximum tenderness is situated over the eleventh rib, about 3 inches from the mid-line, and those where the tenderness is situated lower down to the right, and often extending to the left of the second lumbar vertebra. The tenderness over the eleventh rib has been found in all cases of cholecystitis that I have examined; I believe it to be due to the spread of inflammation first to the parietal peritoneum, and then, via the extra-peritoneal lymphatics, to this point, which is the most dependent when the patient is lying down. The lower area of tenderness occurs in its maximum intensity in cases of acute pancreatitis. It occurs only in a minority of cases of gall-bladder disease, but is always associated with other definite signs of pancreatic disturbance. In my opinion it is due to an inflammatory lesion of the pancreas.

Other areas of deep tenderness to which attention has been drawn by various authors are over the spines of the fifth, sixth, seventh, and eighth thoracic vertebræ, and over the inferior angle of the left scapula. Tenderness in these regions is by no means as marked as that which occurs over the eleventh right rib, and is present in the more severe forms of biliary dyspepsia and is most marked after an attack of vomiting. Tenderness in these two places can be found in all cases of gastric ulcer, which occur proximal to the pylorus. It seems, therefore that it is due to an inflammatory lesion of the stomach. Finally, deep tenderness may be found over the distribution of the right superficial cervical plexus.

On percussion and auscultation valuable information may be obtained of gastric disturbance. In all cases of biliary dyspepsia, and practically all cases of gall-stones, the stomach is found to be enlarged.

X Ray Findings.—X ray examination of the stomach, after introduction of a barium meal, shows dilation of the stomach and evidence of pylorospasm. When examined on the screen regurgitation through the pylorus is seen to be much more marked, and to occur much earlier than in the case in normal digestion.

Chemical Pathology.

The clinical evidence already deduced of stomach and pancreatic disturbance lead to deductions which would have to be regarded as theoretical unless chemical pathology demonstrated their truth. In this branch of the research I have worked with Dr. Mackenzie Wallis, who has conducted all the laboratory investigations and with whom I hope shortly to publish a complete account of our work.

Test-Meal.—The examination of a large number of simple test-meals extracted after one hour's digestion in the stomach has shown that in over 90 per cent. of all cases of gall-stones there is definite hyperchlorhydria associated with regurgitation. In only two cases have we found true hypochlorhydria. Occasionally it was found that there was definite hyperchlorhydria without any evidence of regurgitation. In these cases there was clinical evidence of pylorospasm. We have not found the fractional test-meal of value in the investigation of gall-bladder disease, owing to the difficulty in determining the amount of regurgitation.

Tests of Pancreatic Sufficiency.—The estimation of the amount of diastase in the urine has proved the most delicate test of pancreatic error that we possess. In the normal person the amount of diastase varies between 10 and 30 units, with an average of about 22·5. In our series of cases we have found that in 28 per cent. of cases the diastase has risen to between 50 and 100 units, being always high in cases associated with acute inflammatory lesions of the gall-bladder, and in cases where diarrhœa is a symptom. The amount of diastase in the urine of an individual patient varies from time to time, and is an indication of the varying degree of pancreatic inflammation.

Glycosuria is rare, and has only been found in some of those cases where there has been extensive destruction of the pancreas as a result of sclerosing pancreatitis or acute hæmorrhagic pancreatitis. Indicanuria in varying degree is present in all cases of old-standing gall-bladder disease. It may be stated that bacterial decomposition taking place in the digestive tract and giving rise to the indicanuria is the cause of the diseased gall-bladder. The probability is that a vicious circle is established, and whichever is primary at the onset, in the later stages the interference with pancreatic digestion from the maladmixture of bile predisposes towards intestinal putrefaction, and organisms carried away by the portal stream and eliminated by the liver are a constant source of reinfection to the gall-bladder. Steatorrhœa is found in all cases of obstructive jaundice, and in cases of advanced sclerosing pancreatitis, and in that form of catarrhal pancreatitis whose presence is indicated clinically by diarrhœa. Steatorrhœa is due to lack of pancreatic lipase or its incomplete activation owing to the lack of bile. Loewe's mydriasis test has been positive in only a minority of cases, but in these there has always been other definite evidence of pancreatic insufficiency.

Conclusions.

I have endeavoured to show that the gall-bladder is only a unit in a definite digestive complex embracing the liver, gall-bladder, pancreas, and stomach, and that any disease affecting one unit is bound to be reflected in the whole system. A careful analysis of the history and clinical examination of a patient suffering from disease of the gall-bladder will reveal many points indicative of involvement of the stomach and the pancreas, but which none the less point to the original trouble. Infection of the gall-bladder acting reflexly through the vagus nerve tends to cause hyperchlorhydria and regurgitation. In some cases, where the sensory stimulus is greater, pylorospasm is the result of a sympathetic reflex through the ninth thoracic segment. Regurgitation from the duodenum may also be attributed to the unregulated flow of bile in cases where a gall-bladder is no longer capable of acting as a reservoir.

The pancreas is peculiarly prone to infection from the gall-bladder. In the majority of cases infection occurs through the lymphatics, in others by the regurgitation of bile along the main duct consequent upon obstruction at the ampulla of Vater. This obstruction is frequently due to spasm of Oddi's sphincter and occurs with pylorospasm. The secretion of the pancreas into the duodenum is seldom markedly diminished, the exception being in cases of catarrhal pancreatitis, but through lack of adequate admixture of bile the digestive function of the pancreatic juice may be seriously diminished.

The internal secretion of the pancreas, except in very rare cases—e.g., pancreatic necrosis—is not very much upset, although the increased amount of diastase in the urine and occasional positive Loewe's reaction are indications of some slight alteration.

It will be seen that in some obscure cases of gall-bladder disease, where the cause cannot be found by the ordinary clinical methods, exhaustive examination of the functions of the stomach and the pancreas may lead to a correct diagnosis.

An Address

[ABRIDGED]

ON

PROGRESS AND PROBLEMS IN EPIDEMIOLOGY.

The Presidential Address delivered before the Section of Epidemiology and State Medicine of the Royal Society of Medicine on Feb. 2nd, 1923,

By RICHARD J. REECE, C.B., M.D., M.R.C.P., D.P.H.

My first duty is to thank the Section of Epidemiology and State Medicine of the Royal Society of Medicine for the very great honour conferred on me by the members in electing me to the important position of President, and my second is to offer my apologies to the section for the delay that has occurred in the delivery of the customary Presidential address. To what extent and with what success this Society has contributed to the science of epidemiology and to medical literature can be realised by reference to the index of the papers that have been read at its meetings and to the reports of its various committees which have been formed from time to time for the purpose of studying special branches of epidemiology, but there is yet much to be learnt and many problems remain to be solved.

While the Society's transactions bear witness to the wide range of subjects considered at its meetings and to the merit of the contributions furnished by its members to the study of epidemiology, they also testify that many of the most important papers have been written by medical officers of the Royal Navy, the Army, and the Colonial services, and by medical men who have not served in any of the State medical services, but without in any way detracting from the value or minimising the high esteem that is due, and deservedly due, to the work of these men, it can be said that the elucidation of epidemiological problems has been closely associated with the public health department of the Civil Service.

The Foundation of the Society.

The birth of our Society in 1850 took place at a time when John Simon had commenced to write, and the medical staff of the Privy Council came into existence. To this staff belonged Netten Radcliffe, George Buchanan, and others, the value of whose epidemiological work cannot be overrated. When the State Medical Department was transferred to the newly constituted Local Government Board in 1871, other men joined the service, and the study of epidemiology was continued by Power, Thorne-Thorne, Ballard, Barry, Parsons, T. W. Thompson, Theodore Thomson, Bulstrode, and many more whose names are household words in this Society. Only last year one of our members, who joined the Society in 1887, departed from us, my old colleague, Robert Bruce Low, who by his industry, skill, and perseverance materially assisted the advancement of our knowledge in regard to the prevalence and distribution of disease throughout the world.

When our Society was first instituted it advocated adequate endowment for medical research. We cannot claim that such a proposition emanated solely from our Society; it has been advanced by others, but we can congratulate ourselves that with the advent of the Medical Research Council, one of its primary objects has been fulfilled. The science of epidemiology is not limited to one country, it embraces the whole world; it is not confined to one race of man, nor, indeed, to mankind alone, it extends to the animal and vegetable kingdoms. It is closely associated with geography and history, with the work of the physiologist, pathologist, bacteriologist, and chemist, with the science of statistics, and with clinical medicine. Its interests are far-reaching and our Society, founded for its study, can look forward with satisfaction to the progress our branch of medicine is bound to make as a result of the comprehensive work carried out under the auspices of the Medical Research Council.

Sir Patrick Manson's Views on Future Lines of Research.

In his Presidential Address to this Society in November, 1900, Sir Patrick Manson set forth what he thought should be the future lines of research in the elucidation of the many epidemiological problems brought prominently before the world by having to include the protozoa and nematodes among the important pathogenetic organisms affecting man, and by the knowledge that many diseases are spread in a variety of ways by blood-sucking arthropods. He considered that each problem, after thoughtful formulation, should be carefully worked out by a special investigation. He expressed the opinion that this was the only way to advance, as it was the only way to economise the somewhat limited supply of pathological and epidemiological energy in the market, and that as each investigation would probably extend over a considerable period, probably one or two years, in order to secure continuity of work and to minimise risk of interruption by ill-health or other contingencies, it would be better to have two investigators for each subject. During the 22 years that have elapsed since Manson delivered the address there has been considerable stimulus in the study of pathology and bacteriology, sciences that directly improve our knowledge of epidemic disease though not of the epidemicity of disease. Many workers have entered these fields of study, but it cannot be said that there has been any comparable influx of workers in the domains of epidemiology. There are few men who have the time and opportunity to devote to this science, and however rich the reward that may fall to the successful worker from the fact that he has materially assisted in advancing knowledge and in affording relief to suffering humanity, it is nevertheless a sad truism that, judged on the sordid basis of finance, there are other branches of medicine that are more remunerative.

INTERCOMMUNICABLE DISEASES.

Manson's early work on filariasis gave an enormous stimulus to the study to the part that insect life plays in the transmission of disease to man and has resulted in definitely linking up certain diseases with blood-sucking flies; malaria, yellow fever, sleeping sickness, dengue, and the maggot disease of Trinidad and Central and South America are instances of this, and if we turn to diseases that are spread from animals to man, we have an instance of the effect of a legal enactment, within a short period of time from it being put into operation, having the direct result of eliminating a disease from our midst. This is the Rabies (Muzzling of Dogs) Order of the Board of Agriculture and Fisheries which was first put into operation in 1889, and which was in force in one or another part of the country for 15 years. As the result of its enforcement and through the restrictions placed on the introduction of dogs from abroad, hydrophobia ceased to exist in this country, and for a period of 15 years we were free from the disease. Reintroduced during the war period in 1918, the infection speedily disappeared on the re-enactment of the Order, and the Order was withdrawn finally in 1922.

While it is generally accepted that the milk of cows suffering from tuberculous disease of the udder is capable of conveying tuberculosis to man, we see an extraordinary attitude on the part, not only of the medical profession, but also of the veterinary profession to reject any suggestion that the milk of cows can convey other disease conditions to man. An instance of this is the group of symptoms closely allied to those which we are accustomed to associate with the malady known as scarlet fever and which, from the fact that the inculpated cows were at a farm at Hendon, became known as the Hendon cow disease. The reasoned plea advanced that the observed illness in man was the direct outcome of the consumption of the milk of the affected cows was combated with a strenuousness which was remarkable. The opposition to the theory that such a disease in man could be acquired through the consumption of specifically infected milk remains, notwithstanding that the application of the discovery of Horrocks that Malta fever was spread by goats acting through their milk had the immediate effect of eliminating a milk-borne disease which for many years had materially impaired the military efficiency of the British garrison at Malta.

Anthrax is another disease that is communicated directly or indirectly from infected animals to man, but in it the infection is limited to the individual and does not spread from him to the community. For many years it has been known that the infection can be acquired by man through handling specifically infected skins. An instance occurred during the war in which Prof. J. F. Tulloch, of Dundee, then a lieutenant in the Royal Army Medical Corps, found the *Bacillus anthracis* in the cerebro-spinal fluid of a man who was thought to have died of cerebro-spinal fever, and on continuing his investigation he was able to demonstrate that the infection had been acquired through the respiratory tract. By so doing he added another link to the chain of evidence that anthrax is one of the diseases that is air-borne. A more recent instance in connexion with anthrax which is of interest is that of a man who died of anthrax, and who, immediately prior to his fatal illness, had been engaged in unloading bone meal from a vessel in one of the London docks. Colonel P. G. Stock, who investigated the matter, was able to produce evidence that certain samples of the bone meal obtained from the cargo of the vessel were infected with anthrax, and the question at once arises whether the sporadic outbreaks of anthrax that occur among animals in this country are associated with the use of bone meal for manure.

Recent researches have demonstrated the part played by the rat in rat-bite fever, epidemic jaundice, trichinosis, and septic pneumonia, whilst the known fact that the rat-flea is responsible for conveying the infection of plague has in great measure directed preventive measures against the rodent rather than against man, so far as the bubonic and perhaps the septicæmic form of the disease is concerned. As the result of researches into relationship of the flea to the rat, and of the rat to man, plague came to be regarded from the point of view of epidemiology as essentially a rat disease in which human beings may participate. The Advisory Committee for plague investigation in India concluded their interim report of 1910 with the statement that "In districts which suffer annual epidemics of plague, the rat epidemic, on which the human epidemic depends, occurs during some part of that season when the prevalence of fleas is greatest." The seasonal prevalence of plague is therefore dependent on the life-history of the flea.

THE PART OF THE HUMAN "CARRIER" IN INFECTIOUS DISEASE.

When it became known, primarily through the work of bacteriologists, that man as a "carrier" played a part in the spread of infectious disease, a new problem in epidemiology presented itself and inspired fresh efforts to cope with it. Nevertheless a warning was forthcoming from the epidemiologist that the discovery should not be relied on as a final solution of disease causation. The carrier subject was eagerly investigated by the bacteriologist, experimental pathologist, and public health administrator. Enteric fever, paratyphoid, cholera, dysentery, cerebro-spinal fever, poliomyelitis, diphtheria, pneumococcus-pneumonia, influenza, were all subjected to close scrutiny with the object of obtaining effective control over these diseases. It became recognised that there were two types of carriers, the transitory carrier and the chronic carrier, and that the latter may be the subject of periodical recurrences during which he may be peculiarly liable to spread infection. It was thought that he was responsible for the persistence of infection in endemic form and for recrudescence of infection in epidemic or explosive form.

But we are far from understanding the part played by the diphtheria carrier, and while we know that a large number of diphtheria carriers exist it is only occasionally that a carrier transmits the clinical disease to others. The test of virulence of the *B. diphtheriæ* to guinea-pigs is not entirely satisfactory, for although definite strains of *B. diphtheriæ* may prove fatal to guinea-pigs, it does not follow that these virulent strains when harboured by a carrier are those that enable him to transmit clinical diphtheria to other persons.

SEASONAL INCIDENCE OF CERTAIN DISEASES.

We can state without possibility of contradiction that certain diseases have a seasonal incidence. If we take two such diseases with which we are familiar in this country, we can say that in England whooping-cough is prevalent in the first half of the year and scarlet fever in the last half of the year, but we can give no definite reason for this fact. We can say that one is a disease of the spring, and the other of the autumn. Although it has been suggested that the infection of one of these two diseases—viz., scarlet fever—may be conveyed by the domestic flea, most of us believe, rightly or wrongly, that the infection of these diseases is acquired mainly through the naso-pharyngeal tract, and that in the majority of cases it is transmitted from person to person. But even if this is true it adds to the difficulty of explaining why one is a disease of cold weather and the other of warm weather. The explanation will probably be forthcoming when once the cause of the infection is known.

We are still without definite knowledge of the causative micro-organism of small-pox, chicken-pox, scarlet fever, measles, typhus fever, and, perhaps, to this list influenza may be added. We believe that these diseases, with the exception of typhus, are transmitted directly from person to person without the intervention of any insect carrier. At one time, and until quite recently, we thought that the infection of typhus was communicated in like fashion. Now we know that the infection is transmitted by a biting insect, the louse. Poverty and want and times of famine have been recognised for many years as associated with epidemic prevalence of typhus, and we can appreciate the fact that verminous conditions of persons are allied with such occurrences, and that the verminous condition accounts for instances that have been observed when typhus has been prevalent, and when famine and destitution have been absent. With the knowledge that lousiness must be fairly common among certain classes in Ireland, as evidenced by the fact that some 60 per cent. of Irish emigrants who are now arriving in Liverpool on their way to America and Canada are found to be verminous, we can realise that the absence of widespread prevalence of typhus fever in Ireland must be due to the fact that the causative agent of the disease is lacking.

If we turn to diseases which are definitely associated with a causative micro-organism we can include in the number cerebro-spinal fever, enteric fever, diphtheria, cholera, and plague, and excepting plague each of these diseases is associated with the "carrier" problem. Whether or no there are carriers of cholera who can be classed as "chronic" carriers we have no precise information, but we know that chronic carriers occur in regard to the other three diseases.

In dealing with epidemic and pandemic disease, while it is evident that antecedent or existing causes must have been in operation, we cannot as yet say that we are familiar with them. While we know that certain diseases are prone to a cyclical recurrence we do not yet know what causes are responsible for this recurring cycle of disease prevalence. It is not sufficient explanation to say that epidemics of measles are due to an increase in susceptible material, of children born since the last epidemic, for this would not account for the seasonal prevalence of measles, and still less would it explain the widespread and sudden prevalence of epidemics of influenza throughout the world, during which persons who have passed through a previous attack are again affected.

It may be that certain atmospheric conditions so affect the human constitution as to lessen its power of resistance to disease or that certain low forms of life that we know to be active agents in disease production acquire an additional increase in virulence and power of propagation under differing conditions of the atmosphere not solely referable to changes in temperature. It has been observed on occasions of epidemic prevalence of small-pox that vaccine lymph has appeared to possess undue potency, as shown by the result of vaccination of persons, and that this cannot altogether be explained by a want of due care in the performance of the operation of vaccination which is prone to be associated with panic vaccination. It may be that at such times the susceptibility of the individual to "vaccinia" or to contract small-pox is increased.

"CONTAGIUM VIVUM" AN ESTABLISHED FACT.

The belief in a living cause of disease or contagium vivum is very old. We cannot fail to realise that undoubtedly the greatest progress made in recent years in our knowledge of epidemiology has been the translation of this belief into an established fact; and that this has resulted from the genius of Pasteur in expounding the germ theory of the causation and course of disease, and from the discoveries of Laveran, Manson, and Ronald Ross as to the part played by parasites and insect carriers in disease production. While all this serves to explain endemic forms of disease it does not account for the rapid diffusion and widespread prevalence of disease in epidemic or pandemic form. The essential cause of epidemic diffusion of disease must be dependent on some other factor or factors. There must be something superadded to the disease-producing organisms that augments their virulence or power to affect man; or that increases the susceptibility of the individual or diminishes his power of resistance. The nature of the influence in operation and the necessary part that it plays is unknown.

One cannot fail to be impressed with the persistence of our forefathers that the condition of the atmosphere is in some way responsible for the presence or the absence of disease in epidemic form. At the same time, we must confess that meteorology has hitherto thrown little light on the subject, and notwithstanding the present delicate and far-reaching chemical and physical methods that have been employed in the investigations of the condition of the atmosphere and the magnetic currents of earth and air, these means have entirely failed to show any relation between the physical properties of the air and epidemics of disease.

It is common knowledge that during times of thunderstorms milk readily turns sour. At such times the atmosphere may be charged with moisture, its temperature raised, and so forth. But in like conditions of the atmosphere and in the absence of thunderstorms milk remains unaffected. There appears to be no explanation of this save in the electrical condition of the atmosphere, and if this is the factor that determines the observed phenomenon, knowledge of the manner in which it acts is lacking. Can it be that the acid-producing micro-organisms are stimulated into increased activity through the electrical condition of the atmosphere?

There is another matter which has relation to this subject—namely, the preparation in starch factories of rice starch for laundry purposes. After the starch has been ground into a paste to which water is added, it is further washed with dilute caustic soda to dissolve out more nitrogenous matter (the glutin). At all stages from the rice paste to the final washing the liquid is kept alkaline with caustic soda. It is a well recognised fact that to maintain this alkalinity more caustic soda is required in hot weather than in cold, and further, that in hot weather, when there is thunder in the air, still more caustic soda is required. Under such weather conditions it is not an unusual practice to add formalin to the rice paste to prevent it "turning sour."

The late Dr. R. W. S. Bishop, writing of his experience as a country practitioner at Kirkby Malzeard in the moorland district of Yorkshire, states that "Influenza spreads sometimes so rapidly, especially on the exposed tablelands, that I am perfectly certain climatic influences played a much greater part in its causation than personal contagion." Similar experiences of almost simultaneous occurrence of the disease over wide tracts of land have been recorded by other observers, and these accounts can be considered in conjunction with narratives of ships at sea, that have held no communication with the land and on board of which outbreaks of influenza have occurred at times when the malady has been prevalent on the coasts nearest to the position of the ships. Can the explanation be that the causal agent of the disease in harmless form is harboured by man until some atmospheric condition affords it virulence? Does it militate against such a theory that the disease may break out among islanders two or three days after the arrival of a ship from a foreign port under circumstances that suggest the spread of the malady by direct infection from person to person?

CONCLUSION.

Although from such knowledge as the medical profession has possessed at any given period, it has been argued that this or that circumstance cannot affect the prevalence or the absence of disease, yet these circumstances should be reviewed from time to time in order to ascertain whether recent discoveries in medicine or in allied subjects may supply information that in some way or another may assist to unravel one of the multitude of epidemiological problems. If we direct our attention to the discoveries which of recent years have followed investigation in regard to the physical and electrical conditions of the atmosphere we realise the important results that have followed the practical application of these discoveries to the business of the world. Surely such discoveries should arouse a spirit of inquiry among students of epidemiology and should lead to a reopening of the question of atmospheric influence on the prevalence, and particularly on the epidemic prevalence, of disease. The difficulties associated with such an investigation are great, and much time would necessarily be occupied in a systematic attempt to carry the undertaking through, but though it extends to a sphere that to us may seem immeasurable and one that has only been explored to a very limited extent, such an inquiry after truth might obtain confirmation of an anciently conceived opinion. It might result in filling in, in some measure, the scheme of epidemic diffusion of disease sketched in broad outline by Hippocrates more than 2000 years ago.

Progress in the study of epidemiology is closely associated with precise observations in the wide realm of Nature and in the correct interpretation of these observations. This requires time and opportunity, patience and perseverance, enterprise and experience. There is nothing new or startling in this statement; it is 250 years since Sydenham wrote "true practice consists in the observations of nature."

The student in epidemiology can in all humility echo the avowal made by Fracastor 400 years ago: "I am well aware that it is difficult to say what Heaven does effect and in what fashion, and to find a certain assured cause for every event."

PERNICIOUS ANÆMIA:

AN ANALYSIS OF 117 CASES.

By P. N. PANTON, M.B., B.Ch. Camb.,
DIRECTOR OF HALE CLINICAL LABORATORIES;

A. G. MAITLAND-JONES, M.D., M.R.C.P. Lond.,
SECOND ASSISTANT, MEDICAL UNIT, LONDON HOSPITAL;

AND

GEORGE RIDDOCH, M.D. Aberd., M.R.C.P. Lond.,
FIRST ASSISTANT, MEDICAL UNIT, LONDON HOSPITAL.

(*From the Medical Unit and Clinical Laboratories of the London Hospital.*)

This paper is a critical analysis of cases of pernicious anæmia admitted to the London Hospital between the years 1911 to 1920 inclusive. The cases studied are consecutive, and the clinical records have been carefully examined to exclude those that we consider doubtful; further, we have not included certain rare disorders related to pernicious anæmia, intending to present them in a subsequent paper.

Definition of Pernicious Anæmia.

It is obvious at the outset that the difficulty of defining the term "pernicious anæmia" has to be met. Such definition must include the grounds upon which we make our diagnosis, since it is evident in reading other descriptions of pernicious anæmia that cases are included which we would not ourselves consider to be examples of the disorder. We would describe the disorder as one of grave progressive anæmia for which we find no adequate explanation either in the patient's history or in our purely clinical examination. Not only is there no evidence of external blood loss but such indications of acute internal hæmolysis as deep jaundice and hæmoglobinuria are lacking; ordinary clinical evidence of hæmolysis being confined to a faint tinging of the skin not amounting to icterus and a faint discolouration of the blood serum. Further, this clinical state is associated with a constant and well-defined blood picture, of which the main features are a low red-cell count with a high colour-index, together with the presence of abnormal red cells in the peripheral circulation, and more particularly the appearance of megaloblasts. It is this association of clinical state with blood picture that defines the disorder and renders the diagnosis comparatively simple in the great majority of cases. The clinical state alone may occur with a very different pathological process, as in aplastic anæmia, where the main change results not so much from hæmolysis as from red-marrow destruction, or the blood state alone may be exactly paralleled as in AsH_3 poisoning, when the clinical condition is different. Associated with this combination of clinical state and blood picture are very constant and characteristic post-mortem findings, of which the more important are fatty degeneration, free iron pigment in the internal viscera, and hyperplasia of the red marrow.

Details of Series of Cases.

In this series of cases all examinations of the blood have been made under the direction of one of us; the histories and physical signs have been recorded by many observers, and on this account some inaccuracies must inevitably exist. The cases numbered 117 in all and showed the following facts:—

Sex.—Males 68, females 49.

Age.—The average age on admission was 46, with extremes of 20 and 68. No example of pernicious anæmia in childhood has been observed by us during the last 14 years, and among these 117 cases only 12 were less than 30 years of age.

Nationality.—Of the 117 cases, one was a German, six were Hebrews, and the remainder apparently of British nationality. The figures may be inaccurate, as in some cases no specific notes were made as to the patient's nationality.

Occupation.—Nothing was noteworthy in this respect. One patient, the youngest in the series, worked in a chemical manure factory and one was a gas-worker, but no ætiological relationship between the nature of the work and the disorder could be established.

Duration of Symptoms.—This was difficult to estimate, the onset of the disorder being so gradual; as far as could be determined, however, the average duration of symptoms up to admission to hospital was 17 months, the two extremes being seven days and six years.

1. *General Symptoms and Signs.*

(*a*) *Weakness.*—One hundred and seven patients complained of this symptom, and in 49 it was the chief complaint.

(*b*) *Change of Colour.*—Thirty-three patients had noticed a change of colour; eight of these described this change as jaundice. Whilst in hospital five patients were noted to be jaundiced; in three of these the jaundice was described as being slight in amount and bile pigment was not present in the urine or serum. In two patients only was well-marked jaundice present, and these showed bile in the urine and serum. In neither of the latter was the diagnosis confirmed post mortem. In all the patients a change of colour was noted, and in 57 the change was described as being of the classical lemon-yellow tint. The above facts accorded with our own expectation, since we consider jaundice to be rare in this disorder and have frequently observed a simple pallor to be substituted for the lemon-yellow tint. Deposition of pigment was observed in ten patients in the series, but though we are unable to exclude arsenic as an ætiological factor in all of these cases, we have satisfied ourselves that pigmentation, both local and diffuse, does occur without arsenical medication. Pigmentation of mucous membrane was not recorded.

(*c*) *Loss of Weight.*—The primary complaint of eight patients was loss of weight, and 26 cases were noted as being wasted. This point is often overlooked, and while patients as a rule are well nourished some loss of weight frequently occurs, and in a few cases is marked.

(*d*) *Pyrexia.*—Fever was noted at one time or another in 90 cases, the average range being from 99°–100° F. It was noticed in studying the temperature charts that improvement in a patient's condition was as a rule synchronous with the disappearance of the fever. Further, the more acute the case, the more constant was the presence of the fever. While the very frequent association of pyrexia with pernicious anæmia has suggested an infective origin for the disorder, we would point out that internal hæmolysis alone is sufficient to account for the fever.

2. *Local Symptoms and Signs.*

(*a*) *Gastro-intestinal System.*—Eighty-six patients complained of symptoms referable to this system; in 53 complaints of this nature were primary. In considering gastro-intestinal symptoms we are aware of the fact that arsenic had sometimes been given before admission to hospital, but it is probable that this occurred in a few cases only. On analysis, 51 complained of vomiting, 30 of diarrhœa, 26 of anorexia, and 24 of epigastric pain. In certain cases diarrhœa was very prominent and formed the prelude to the train of symptoms. Various other complaints, such as nausea and constipation, were also given in the histories. Only eight patients complained of a painful tongue and in three of these this was the first symptom noticed. In our personally observed instances of pernicious anæmia, we have been struck by the frequency with which patients on being questioned admit that a sore tongue has at one time or another been present. And it must be noted that in the series of cases which form the basis of this paper a specific inquiry had been directed to this point in 34 instances only. Hence the available evidence upon which the frequency of this symptom could be gauged is insufficient. The associated atrophy of the tongue is well known and has been described by many observers and in particular by Hunter,[1] and recently by Sakheim.[2] Atrophic glossitis is not invariably present, and we have seen the typical changes in a patient without pernicious anæmia. It is stated by Hirschfeld[3] to be absent in bothriocephalus anæmia.

Oral Sepsis.—We have investigated as far as possible from these records the frequency of oral sepsis, and we are confronted by the difficulty of appraising what is exactly meant by this term. Of the 117 cases the state of the mouth is unknown in 13, and pyorrhœa was said to be present in 47. In addition, 13 patients had false teeth, 2 were edentulous, and 3 were noted as having few teeth. In 10 cases mention was made of carious teeth; in 8 cases the adjective "fair" was applied to the state of the mouth; in 12 cases the teeth were described as "clean"; and in 9 cases as "good." In this series, then, of 104 cases investigated on this point, in 21 only was the mouth described as free from sepsis. For purposes of comparison we have examined the mouths of 100 adults over the age of 25 in the medical wards of the London Hospital, and found that 37 had pyorrhœa, 29 had carious teeth, 20 were edentulous, and 14 had clean teeth free from sepsis. We are not of the opinion that oral sepsis has any proven ætiological significance in pernicious anæmia, although we freely admit that it cannot but be detrimental to a patient's health and may at times produce a secondary anæmia such as is caused by any other chronic suppurative process.

Gastric Secretion.—Thirty-five patients in this series were given Ewald test-meals, and in 33 there was achylia. In two patients only was free hydrochloric acid present in the test-meal filtrate; in the first it reached 0·1 per cent. with a total acidity of 43, and in the second there was a trace only with a total acidity of 35. The average total acidity of the remaining 33 cases was 10. The achylia with associated atrophy of the gastric mucous membrane seen in this disorder has attracted considerable attention, and in regard to this subject the following facts can be stated: That pernicious anæmia may occur, though rarely, without achylia; that achylia frequently occurs without pernicious anæmia; that a severe secondary anæmia, if sufficiently prolonged, may be followed by achylia and although the anæmia may be cured the achylia may persist; and that the growth of ordinary aerobic and anaerobic bacteria is prevented in a medium with an acidity represented by a positive Töpfer reaction. With these facts before us we state, somewhat tentatively, our view that while the very frequent occurrence of achylia is noteworthy and may of itself assist or even predispose towards the morbid process, we must look elsewhere for the essential ætiological factor.

Hæmatemesis.—This was complained of by three patients, and in one instance only was it copious. In this patient post-mortem examination substantiated the diagnosis of pernicious anæmia. Each of the other two patients vomited a drachm or so of blood on one occasion. All these were females.

Spleen.—The spleen was stated to be palpable in 21 cases, and the liver enlarged in 19.

(*b*) *Cardio-vascular System.*—Sixty-three patients complained of symptoms under this heading—shortness of breath on exertion, palpitation, and attacks of syncope being the main features. Sixty-two patients on examination were found to have cardiac murmurs.

(*c*) *Central Nervous System.*—Twenty-five patients complained of headache and 18 of numbness and tingling of the hands and feet. To the symptom of headache we attach no particular significance, Paræsthesiæ, however, are important, but unfortunately the difficulty that was met with in considering gastro-intestinal symptoms is again encountered here, and we are unable to exclude the influence of arsenic as a causative factor. These records of the examination of the central nervous system are not sufficiently full or uniform to justify us in drawing any conclusions, and we intend to enter into the question of subacute combined degeneration in a separate paper.

(*d*) *Genito-Urinary System.*—No symptoms worthy of note were described. Albuminuria was present in 24 patients, two passed bile pigment in the urine, and one showed glycosuria. An account of this last patient was given by Parkinson* in 1910. In no case in this series was pregnancy associated with the anæmia. The relationship of pregnancy to severe anæmia raises questions of interest which will be referred to in a subsequent paper.

(*e*) *Blood.*—We consider that our figures relating to the examination of the blood are trustworthy in so far as a uniform method of examination in the laboratory has been practised throughout under the direction of one of the authors. In one case only the blood was not examined. This patient, a male, aged 64, was moribund when admitted; there was an 18 months' history of change of colour, weakness, and loss of weight, and the autopsy showed the characteristic changes of pernicious anæmia. The blood examinations carried out on the 116 cases show on analysis the following figures:—

(1) *Red Corpuscles.*—The average count on the first admission was 1,387,312 per c.mm. with extremes of 500,000 per c.mm. and 3,370,000 per c.mm. The average count on discharge was 2,443,365 per c.mm. The average count for patients readmitted for the second time was 1,295,718 per c.mm., and on their second discharge 2,008,333 per c.mm. These figures are interesting from two points of view. First, they emphasise the fact that patients seek admission to hospital when the number of their red cells falls to the neighbourhood of 1,000,000 per c.mm. Secondly, the figures bring out the point that, although patients were usually discharged in an improved clinical condition, this did not correspond with any great increase in the number of red cells, the average count on discharge exceeding the average count on admission by approximately one million only. This fact is in harmony with our own observations, as we consider that in this disorder a return of the number of red cells to the normal is extremely rare. Megaloblasts were found in 92 out of 116 cases. Of the remaining 24 cases, 12 were in hospital for a short time only before death, and in none of the remainder were periodic examinations made thoughout the illness. We conclude that megaloblasts are probably present at some period of the disorder, even though they may not be found at one or more examinations. No actual measurement was made of the average size of the

---

* THE LANCET, 1910, ii., 543.

red corpuscles, which were on several occasions noted to have appeared larger than normal.

(2) *White Corpuscles.*—The average total leucocyte count on admission was 3378 per c.mm. with extremes of 600 per c.mm. and 14,000 per c.mm. The average percentage of lymphocytes was 41·3, and of eosinophils 1·7. We consider leucopœnia with a relative lymphocytosis to be an important diagnostic feature of the blood count, but one must admit that the average percentage of lymphocytes in these cases is not entirely outside the normal range.

(3) *Colour-Index.*—The average colour-index for all cases on admission was 1·01 with extremes of 0·5 and 1·6. In 15 cases in this series the colour-index was at one time or another below 0·7. In three cases the colour-index was persistently below 0·7 during the whole period of observation. Post-mortem examinations were obtained in these three cases and substantiated the diagnosis. In 87 per cent., therefore, a high colour-index was always found, and in only 2·6 per cent. was the index consistently low. We consider an index of 0·7 with a severe anæmia to be a high one and strongly suggestive of pernicious anæmia.

We should like, whilst considering the blood changes in this disorder, to emphasise as strongly as possible that a diagnosis of pernicious anæmia can only be made from a careful clinical examination combined with a complete and thorough blood examination repeated, if necessary, at intervals. A diagnosis dependent upon the results of examination of a blood film alone is unjustifiable. However complete the clinical investigation may have been the blood examination must always include the enumeration of the total red and white cells and the percentage of hæmoglobin in addition to the histology of the cells.

(*f*) *Remissions.*—We have found it difficult to make any absolute statement as to either the number or the duration of remissions from the evidence afforded by the clinical records of this series of cases. It appears to us, however, that the usual number of remissions is two, and that if this number is exceeded as many as four or five frequently occur. The duration of remissions was on the average about four months and it rarely exceeded nine months. In any series of cases of this disorder there is a certain number in which no remissions occur. In the 111 cases we have traced in this series remissions were absent in 18 and the disorder from its inception ran a steadily progressive course. The average age of the patients in this group was 46, and there were nine males and nine females. Sixteen of these patients died in hospital and post-mortem examinations were performed in nine with findings which confirmed the clinical diagnosis. In a few cases only was the blood examined periodically throughout the illness while in hospital and when back at work. In these patients a notable degree of anæmia persisted during the remissions. In only one case of apparent cure—to be referred to later—have we been able to detect an entirely normal blood count during any period of observation.

(*g*) *Duration and Prognosis.*—One hundred and eleven cases out of the total of 117 have been traced up to the present time, and of these eight only are still alive. In this connexion we purposely chose the period 1909 to 1920 in order to afford the best opportunity of following the great majority of our cases to the end. The number of patients lost sight of is six, which we consider to be very small for this class of patient, and by disregarding this number while considering the duration and mortality it is probable that our error is very small, the missing patients being evenly distributed over the period. The eight surviving patients may be divided into the following groups: 1. Recent cases running the usual course. There are two in this group, Nos. 105 and 106, both recently reported to be "progressing favourably" but not recovered sufficiently to return to work. 2. Chronic type with relapses—three examples, all women—in whom the blood is still typical of pernicious anæmia; the clinical state fluctuates between a period of well-being with ability to work and a state of asthenia requiring hospital treatment. No. 12 dates her illness from May, 1908, and has been under periodic observation since 1909. Nos. 70 and 72 were first admitted in 1915. 3. Arrested type, two cases—Nos. 68 and 86, one female, the other male, each having had periods of more than five years of freedom from symptoms. A recent clinical examination showed in both cases some of the blood changes characteristic of pernicious anæmia, but with high red-cell counts. Symptoms were absent, but complete achylia was present. The nervous system was unaffected. 4. Cured type, of which No. 1 is the only example in this series, and the only instance in our experience of pernicious anæmia in which cure has apparently occurred. This man, a farmer, aged 45, was admitted into the London Hospital in September, 1909, with a four years' history of pallor, dyspepsia, and occasional diarrhœa. He complained of marked weakness and of tingling sensations in his hands and feet. He had a blood count typical of pernicious anæmia with a red-cell count of 700,000 per c.mm., a colour-index of 1·0, and a large number of megaloblasts. Complete achylia was present. There were physical signs which definitely pointed to involvement of the spinal cord. After one month in hospital his red-cell count increased to 4,100,000 per c.mm. with an index of 1·0, and nucleated red cells disappeared. After a brief period of convalescence he returned to work and from that time has never had a day's illness. At the present day his blood is normal, the achylia persists, the subjective and objective signs of involvement of the central nervous system are unaltered, and his physical state is otherwise perfect. A complete remission of 12 years has therefore occurred, and the patient appears to be in perfect health except for minor disabilities resulting from the original attack.

We have divided the remaining 103 cases into two groups, one with remissions and one without. The first group numbers 84 cases, in which the average duration of the disorder from the first symptom was 34 months and from the date of admission to hospital was 15 months. The second group, consisting of those cases without remissions, numbers 19, and the duration was nine months from the beginning of symptoms and six and a half weeks from the date of admission into hospital. It was not surprising to find that only eight patients out of the total of 111 are alive at the present time; rather were we surprised to find so many still surviving. We wish to emphasise this high mortality rate which is in complete accord with our own experience, since it has frequently been suggested that pernicious anæmia is a disorder in which recovery is not rare.

We therefore state that in our opinion recovery from pernicious anæmia is an event of such rarity that it cannot be accepted in any case without the fullest confirmation. With regard to those exceptional patients in whom the disorder has become arrested or apparently cured, we are unable to bring forward any suggestions as to the cause of this arrest or to describe any features by which they can be recognised in the early stage of the illness.

Treatment.

Here we propose to discuss certain aspects only of the treatment of pernicious anæmia.

1. *Oral Sepsis.*—The presence of gross septic infection of the mouth obviously calls for treatment, as it would in any other morbid state; but we wish to enter a protest against the indiscriminate extraction of teeth and to point out that the presence of pernicious anæmia is no indication per se for rendering the patient edentulous. The majority of the patients in this series received the most thorough dental treatment. The condition of some was made miserable by wholesale extractions of the teeth and of these a number survived long enough to contemplate, but not to use, the new dentures. Nor have we satisfied ourselves of the cure of a single example of pernicious anæmia by the treatment of oral sepsis. We would therefore suggest that dental treatment should be limited to definite septic foci and otherwise should so far as possible be conservative.

The treatment of dental sepsis involves a consideration of vaccine therapy. The recent work of McIntosh and Lazarus-Barlow[4] strongly suggests that the bacteria commonly used in the past as the basis of vaccine therapy for oral sepsis are not themselves the cause of dental caries. Our own experience of vaccine therapy in this connexion is that it is rarely, if ever, of any value, and here we would take the strongest possible exception to the advice of Hurst and Bell[5] upon the treatment of pernicious anæmia. These authors advise the use of streptococcal vaccines derived from the mouth, the duodenal contents, the fæces, and the urine. We fail to find any justification for such a procedure.

2. *Achylia.*—The treatment of this condition by the giving of artificial gastric juice is theoretically indicated in the great majority of cases and in practice, if it does not lead to cure, is frequently of value. The large doses of hydrochloric acid recommended by Hurst as the result of his experimental investigations seem to us worthy of trial.

3. *Arsenic.*—This drug, in one form or another, was given to practically all the patients in this series, and it is apparently still regarded as the most effective therapeutic agent that we possess for the treatment of pernicious anæmia. That the drug has no curative action is known; that it has any effective ameliorative action we are inclined to doubt. Patients often continue to deteriorate while taking liquor arsenicalis and may begin to improve suddenly when organic arsenic is substituted for it. The reverse has also been observed. In estimating the effect of arsenic as a therapeutic agent, it is necessary to consider the probability that during a remission a balance is struck between the hæmolytic and regenerative processes. In a relapse the hæmolytic factor is predominant, and tends to remain so until a red count level of 1,000,000 per c.mm. or less is reached. Regeneration then tends to outstrip hæmolysis with a corresponding improvement in the patient's state. It is usually towards the end of a relapse that the patient comes for treatment and arsenic is prescribed. The subsequent improvement which tends spontaneously to occur may be wrongly attributed to the arsenic. One of the patients in this series was treated with arsenic and rapidly improved; but when readmitted later and treated without any drugs at all he made an equally rapid improvement. Although we doubt whether arsenic has any real therapeutic value in pernicious anæmia, in default of any specific remedy for this disorder we continue to use it.

Divergent views, based both upon clinical and experimental observation, have been expressed by a number of writers upon the value of arsenic as a blood-forming agent. These views have recently been summarised by Roch and Katzenlebogen,[6] who give a bibliography bearing upon the question. The summary of these authors, together with the work done by them upon a new organic arsenical preparation —*arsylène*—appears to us to justify the doubt concerning the value of arsenic to which we call attention. Germanium dioxide,[7] which has been shown experimentally to increase the number of red cells, has been found to have no therapeutic value in the treatment of this disorder.

4. *Blood Transfusion.*—A few patients in this series were treated by blood transfusion and we have so treated others. The conclusion to which we have come is that unless for some particular purpose it is advisable to prolong life for a period blood transfusions are inadvisable. When the transfused blood is used up more has to be given, and in our experience we have been unable to detect any evidence of real recovery of the patient's blood-forming tissues to follow the transfusion.

5. *Splenectomy.*—This operation was originally undertaken with a view to the cure of pernicious anæmia, and we have been unable to follow the theory underlying this procedure. More recently William Mayo[8] has advocated splenectomy in the hope not of cure, but of prolongation of life, on the theoretical ground that "the red cells are born feeble" and are therefore too rapidly destroyed by the spleen. His advocacy has been strengthened by Giffin and Szlapka's[9] analysis of the records of 50 patients treated by splenectomy at the Mayo Clinic. We have, so far as possible, compared our figures with those of Giffin and Szlapka. Of our 111 cases which have been traced, 105 were first admitted to hospital more than three years ago; of these 105, one was submitted to splenectomy and is therefore not included. Of these 104 cases, 17, or 16·3 per cent., survived more than three years; of the 17 cases, 11, or 10·6 per cent., survived more than four and a half years, and two others are still alive but having not yet reached the four and a half year limit are not included. The Mayo Clinic figures give an operative mortality in their 50 patients of 6 per cent. Of the 47 survivors 10 patients, or 21·3 per cent., lived more than three years after the operation and 5 patients, or 10·6 per cent., lived more than four and a half years. Giffin and Szlapka therefore omit the operative mortality in estimating the survival period. This is reasonable for the purpose of estimating the effect of splenectomy on the course of the disease, although it would have to be allowed for in advising any patient on the operation. The Mayo Clinic series of cases, therefore, gives for 21·3 per cent. a period of three years and our figures 16·3 per cent., a difference of only 5 per cent. Taking the survival period of four and a half years the figure in each case is 10·6 per cent. These figures are remarkably similar considering the small number of cases concerned, and the conclusion of Giffin and Szlapka that splenectomy prolonged life in at least 20 per cent. of their cases is not substantiated. If, indeed, we compare the class of patient admitted to the Mayo Clinic with that of the London Hospital we shall probably find that the average state on admission is very much less grave in the class of patient admitted to the Mayo Clinic. Patients seen by us for the first time in private practice are almost invariably in a less advanced stage of the disease than hospital patients. We do not therefore consider that any case for splenectomy has been made out.

Diagnosis.

A consideration of all the disorders that have been confused with pernicious anæmia lies outside the scope of this paper, and we propose to limit our discussion to the commoner difficulties in diagnosis. The identification of the disorder is based on two forms of examination—clinical and hæmatological—and we will consider these separately.

Clinical Examination.—It is of primary importance to determine whether there is any demonstrable cause for the patient's illness. A careful inquiry should be made for a history of loss of blood, particularly from the gastro-intestinal tract. A continuous small blood loss from hæmorrhoids or larger intermittent bleedings from a duodenal or gastric ulcer produce at times a clinical picture not unlike pernicious anæmia. Profuse hæmorrhage may, however, occur, though rarely in pernicious anæmia. Gastro-intestinal symptoms are extremely common and are responsible to a large extent for the difficulty in diagnosis between pernicious anæmia and cancer of the stomach. In carcinoma, however, pain is a more prominent feature, whilst in pernicious anæmia the complaint is of discomfort rather than pain. Additional points of importance are the profound anæmia and marked persistent wasting that occur in cancer of the stomach. The languor and weakness with the gastro-intestinal symptoms of pernicious anæmia are at times suggestive of Addison's disease, and the diagnosis may be further confused by the presence of pigmentation which at times occurs in pernicious anæmia. The most helpful differential point clinically is the characteristic lowering of blood pressure in Addison's disease. Two points to which attention should be directed in the history are soreness of the tongue and persistent paræsthesia of the extremities. Either of these two symptoms is suggestive. The general aspect of the patient gives information of value. We believe that in the majority of patients the appearance and colour of the face are very suggestive, but too much emphasis should not be laid on the colour alone. Patients with pernicious anæmia are frequently pallid only, and those with a secondary anæmia of long standing may show a lemon tint. It may be said that, as a rule, the patient with pernicious anæmia looks more ill than he feels, while the patient with secondary anæmia feels more ill than he looks. The state of nutrition should be observed; marked wasting would be favourable to a diagnosis other than pernicious anæmia, although some loss of flesh in this disorder occurs not uncommonly, as we have already pointed out.

The physical examination may show an enlarged spleen and liver, hæmic murmurs, and retinal hæmorrhages. With regard to the spleen, if it becomes enlarged, it is "palpable" only; gross enlargement of this region should suggest a revision of the diagnosis. Confusion has arisen between pernicious anæmia and subacute bacterial endocarditis, as in both disorders, anæmia, pyrexia, cardiac murmurs, and a palpable spleen may be found. We have recently observed a case in which the differential diagnosis was extremely difficult on clinical grounds. The frequent damage to the aortic cusps and kidneys in endocarditis are the factors, apart from the blood examination, which give most assistance in the differential diagnosis. The achylia so often present is of value, and in an obscure case we would hesitate to diagnose pernicious anæmia if free hydrochloric acid could be demonstrated in the test-meal.

On *hæmatological* grounds the blood picture of pernicious anæmia has been sufficiently indicated and is indeed so well recognised as to require no further description here, but it remains to mention certain pathological states in which the blood condition of pernicious anæmia may be more or less closely simulated.

Secondary Anæmia.—Here the low colour-index and absence of megaloblasts give a blood picture entirely distinct from that of pernicious anæmia. It is true that cases arise in which a definite diagnosis may not be possible at one or even two examinations. The colour-index may be low on occasion in pernicious anæmia, and megaloblasts absent. More rarely the index may be high in secondary anæmia, and still more rarely megaloblasts may be present. These points are known and have been unduly laboured. We are unacquainted with such series of cases as are described, for example, by William Hunter,[10] who appears to find hæmatological confusion between the pernicious and secondary types of anæmia a matter of common occurrence. We are not concerned here, as is Hunter[10] in his latest paper, with the question of whether the cord changes so frequently associated with pernicious anæmia are to be found also in secondary anæmia; that is a matter upon which the distinction of the two types of anæmia does not depend and which we also have under investigation. We state that the distinction between primary and secondary anæmia can always be made if our examinations are properly conducted, and we rely for this statement upon the evidence of our investigations. We have covered here a period of 11 years in the records of the London Hospital, a period during which occurred 117 cases of pernicious anæmia and a far greater number of cases of secondary anæmia. Every blood examination in all these cases was made under our direction; nearly all the patients with pernicious anæmia have been followed till death. Large numbers of post-mortem examinations have been made, both in these cases and in cases of secondary anæmia, and in not a single instance have we been able to trace a failure to distinguish between primary and secondary anæmia. We regard this purely as evidence that such distinction is not as a rule difficult, and we admit that at any time an error may occur. We have, indeed, at another period made such an error, through careless observation, on one occasion to our knowledge and possibly on others. Our sole point is that such mistaken diagnoses should be too rare for any one observer to produce a series of them.

Pregnancy.—The puerperium or the period shortly before child-birth may be associated with an anæmia disproportionate to such hæmorrhage or sepsis as may have taken place. The hæmatological picture in these cases may, though rarely, closely simulate that of pernicious anæmia. The appearance of nucleated red cells, including megaloblasts, in the peripheral circulation is common during the puerperium, and though the colour-index is usually low, it may be high. Patients with severe anæmia of this sort frequently recover completely and rapidly regain a normal blood picture. We consider that a diagnosis of pernicious anæmia should never be made in the puerperal woman without the fullest investigation extending over a considerable period.

Myelophthisic Anæmia.—This condition is rare in general hospitals, but possibly quite common in infirmaries or homes for incurables. We have seen several examples of it. The blood film in such cases may be typical of pernicious anæmia, nucleated red cells, including megaloblasts, being often very numerous. The colour-index, however, remains low. The complete blood picture of numerous megaloblasts with a low index is sufficiently striking to have enabled us to make the diagnosis of myelophthisic anæmia from a blood examination alone.

Aplastic Anæmia.—This gives a grave anæmia with high colour-index, but morphological red-cell changes, other than anisocytosis, are absent. The leucopenia and relative lymphocytosis become progressively more extreme in aplastic than in pernicious anæmia.

Arseniuretted Hydrogen Poisoning.—This may give a blood picture identical with that of pernicious anæmia, aut complete recovery to the normal takes place bnd the associated conditions of deep jaundice and hæmoglobinuria are distinctive.

Acholuric Jaundice.—This has the blood picture of secondary anæmia and the diagnostic feature of red cell fragility.

The Leukæmias.—These are readily recognised hæmatologically and only on rare occasions and for a brief period during their course may the question of differential diagnosis from pernicious anæmia arise. The colour-index, usually low, may be high and to such cases, when unaccompanied by a marked leucocytosis, the term leukanæmia has been applied. We doubt the necessity of the term and as a pitfall in diagnosis it is rarely met with and easily avoided.

The Infantile Anæmias.—In infancy and below the age of 10 years all hæmatological diagnosis is difficult. The typical blood picture of pernicious anæmia, however, is very rarely met with in infants. The only close approach to such a picture in our experience was met with in a case of aplastic anæmia in a child.

Unclassified Anæmias.—There are certain rare forms of anæmia which differ clinically from pernicious anæmia, but in their blood picture are identical. We propose to describe such few examples as we are acquainted with in a subsequent paper.

Gastro-intestinal Disorders.—Carcinoma of the stomach has often been stated to give the blood picture of pernicious anæmia. It has happened to us in one week to see two cases diagnosed as pernicious anæmia on clinical and blood-film findings. In both we found the blood changes of secondary anæmia and both were proved to have carcinoma of the stomach. Gastric cancer may exceptionally require particular care to distinguish it from pernicious anæmia, but does not otherwise cause more difficulty than any other form of secondary anæmia. A case of severe anæmia following gastrectomy has been described by Hartman,[11] but the case in question, though of great interest, is not a complete example of pernicious anæmia. Such events require further investigation. Sprue is a condition we have rarely met with, but Dr. H. L. Tidy has informed us of a case in which the blood changes were identically those of pernicious anæmia. Nor have we any personal experience of bothriocephalus anæmia, in which condition the blood changes may be typical of a primary anæmia.

In the preparation of this analysis we have been greatly indebted to the staff of the London Hospital, who have given us free access to all the patients under their care.

INTRATHORACIC CATASTROPHES SIMULATING THE ACUTE ABDOMEN.

BY J. HOGARTH PRINGLE, F.R.C.S. ENG.,
SURGEON, ROYAL INFIRMARY, GLASGOW.

I RECORD the two following cases for two reasons. First, the conditions from which the patients were actually suffering are not common; and secondly, the symptoms presented, on admission to hospital, were so remarkably similar to those one meets with in abdominal emergencies that looking back upon them now I do not see how any other opinion could have been arrived at than that they were both instances of serious intra-abdominal lesions. The first case came under notice in 1909, and until the second patient was seen 13 years later I had met with nothing of the same nature. Nor had I seen any record, or even a suggestion, that symptoms resembling in any degree those of what is known as "the acute abdomen" could present themselves in cases of what one may term "intrathoracic catastrophes."

CASE 1.—A storeman, aged 65, was sent in from the country to the Glasgow Royal Infirmary on Jan. 6th, 1909, with the diagnosis "probable perforation of stomach." The patient had been a heavy drinker, and for the last two years had developed symptoms of gastritis, pain after food, and vomiting, especially after drinking bouts. He had had a heavy drinking bout "at the New Year," and this illness for which he was brought to hospital followed directly upon it. His friends said that on Jan. 2nd he appeared to be dazed and ill, and took little food. He went to his work on the 3rd, although advised not to do so, and he continued at it until mid-day on the 6th, when he was suddenly seized with agonising pain in the epigastric region and collapsed in consequence. He had vomited blood on several occasions, both on the 4th and 5th, but although he vomited several times after the onset of pain on the 6th, we were told there was no blood in the vomitus that day. He did not vomit after admission. A history of biliary colic could not be obtained.

Condition on Examination.—The patient was admitted to hospital ten hours after the onset of pain; he was a big, burly man suffering intense abdominal pain. He held on to his abdomen with both hands, often rubbing the abdominal wall, and begged for operation to get relief. Abdominal wall hard and rigid all over and abdomen a little distended, distension being specially marked in epigastric and hypochondriac areas; slight tenderness over right iliac fossa, but pain and tenderness most severe in epigastric zone. Liver dullness was not diminished. No fullness in Douglas's pouch, and no tenderness elicited on rectal examination. Patient distinctly cyanosed, but not sweating. Heart sounds inaudible owing to noisy breathing, the pulse 118, rather feeble. Temperature 99° F. Respiration mainly thoracic. Leucocyte count 13,200.

Diagnosis.—From the history, the general appearance of the man, and the state of his abdomen, I thought the condition was probably acute pancreatitis rather than perforation of stomach or duodenum. The patient was quickly prepared and taken to the operating theatre, but by the time he got there his general condition had changed so much for the worse that no operation was undertaken. No anæsthetic was given, and he died soon after being put back into bed. one hour and a half after admission.

Post-mortem Examination.—Body remarkably well-developed. Thorax: Pericardium healthy, contained about 1½ oz. deeply blood-stained fluid. Heart enlarged, with a considerable deposit of fat on it. Along distribution of left coronary artery an area of hæmorrhage with softening at parts. Left ventricle hypertrophied, but myocardium appeared of good quality. Valves of heart appeared healthy and competent. Aorta dilated and showed considerable atheroma throughout. On dissection of left coronary artery the orifice was free, but half an inch from this the vessel was completely blocked by thrombus which extended for nearly half an inch, and appeared to arise from a hard, calcareous patch at this region. Beyond this part coronary unobstructed but markedly atheromatous. Right coronary artery free, but lumen narrowed from advanced atheromatous change, much pultaceous matter adhering to scissors when vessel was slit up. In lower part of intraventricular septum extensive necrosis and destruction of the muscular tissue with a large, gaping, irregular orifice communicating with the right ventricle. Almost the entire lower half of septum, yellowish-white in colour, soft, and breaking down on slight pressure. Apart from this, no apparent degeneration of myocardium. Lungs: Left lung free. Pleural cavity contained about 12 oz. blood-stained fluid. Lung healthy on section. Right lung extensively adherent from old pleurisy. Abdomen: Remarkable fatty development all over. Liver adherent to diaphragm over right lobe; slightly fatty on section. Gall-bladder healthy; no gall-stones; spleen and pancreas healthy; kidneys engorged with blood showing some small cysts. Adrenals, bladder, and ureters healthy. Small shallow ulcer near cardiac end of stomach. Intestines normal.

CASE 2.—Labourer, aged 62, sent into the Glasgow Royal Infirmary from the country on Dec. 18th, 1921, with diagnosis of "strangulated left femoral hernia." He stated that ten days before admission he had been engaged on unusually heavy out-door work; he had had a good deal of pain in his neck for seven days, and had been treated during that time for neuritis; he had not worked since the onset of this pain. On the day of admission he wakened at 5 A.M. and stretched himself vigorously in bed, raising his arms above his shoulders in doing so. This movement was followed by the onset of the most agonising pain in the lower abdomen, chiefly felt in the left iliac fossa. He stated that at the moment he had the sensation as of "something giving way in his belly." About an hour later his medical attendant diagnosed his condition as a left femoral hernia and applied taxis for a considerable time without any relief to the patient, whom he then advised to go to hospital. The patient arrived shortly before 11 A.M.

Condition on Examination.—Patient was well-built but spare. His face was drawn, and he was cyanosed. Intense pain immediately above medial extremity of left inguinal ligament; he writhed about in bed and cried out, continually rubbing or holding abdominal wall rather below umbilicus and urgently begged for an operation. Tissues in neighbourhood of left saphenous opening showed signs of recent bruising; a slight fullness there, but no tumour. This region very tender, and on palpation a fine crepitus could be felt—whether due to a small quantity of gas or to fragmenting blood-clot in the tissues I could not determine. No impulse when patient strained. Some enlarged glands under right inguinal ligament. No distension of abdomen, but abdominal muscles absolutely board-like. Respiration chiefly thoracic. A small umbilical hernia and a small epigastric hernia about the size of a cherry; the former reducible, but not the latter. Hepatic dullness normal, no sign of fluid in flanks, nothing abnormal felt by rectal examination. Patient had not vomited, bowels had not moved since onset of pain, but had acted daily up to and including day before admission. Heart sounds, not well heard owing to patient's noisy breathing and groaning, seemed normal. Pulse 84, fair tension; respirations 28; lungs normal. Temperature 98° F. Blood pressure not taken.

Operation.—At the time there were two other cases of "acute abdomen" in the ward to be dealt with, all three patients having been admitted within half an hour and all extremely ill. On account of this man's extreme pain I decided to operate for him first; although the cause of his symptoms was not clear, I thought they might be due to thrombosis of his mesenteric vessels. I could not accept the idea of the femoral hernia, though it seemed advisable to explore the left femoral ring, chiefly because of the crepitation. Anæsthesia was commenced exactly half an hour after he was first brought to the ward. I explored the left femoral ring first, and found the tissues infiltrated with blood but could not recognise any gas in them. The ring was found closed, so the wound was sutured and the abdomen opened, but nothing abnormal beyond the two small ventral herniæ noted above was found. All hernial rings on both sides were closed. The mesenteric vessels, pancreas, spleen, and liver normal. Gall-bladder tense and thin-walled; no stones in it or in the common duct. Bowel showed no sign of constriction.

The patient died rather suddenly two hours after having been put back to bed, the pulse having been quite good up to the time of his collapse; at completion of operation his general condition did not seem any worse than before it was commenced, so that information of his sudden collapse came somewhat as a surprise, and for the first time the possibility of some intrathoracic lesion occurred to me. We were fortunate in obtaining permission for a post-mortem examination.

Post-mortem Examination.—Nothing abnormal in abdomen beyond a few small gall-stones in a very tense gall-bladder and slight interstitial nephritis. Spleen: Signs of perisplenitis of old-standing. All hernial rings closed. Left pleural cavity contained rather more than three pints of blood, partly clotted. Left lung collapsed. Both lungs showed a considerable degree of anthracosis and some hypostatic congestion. Tissues round œsophagus and descending aorta infiltrated with blood-clot down to diaphragm. Left ventricle of heart dilated and hypertrophied. Cardiac muscle flabby. Calcareous deposits along attached convex margin of aortic cusps and also in aorta immediately above. Cusps slightly adherent to each other along their edges. Other valves normal. Coronary arteries showed advanced patchy atheroma with calcareous changes. Aorta did not show extensive disease. Several patches of atheroma near orifices of intercostal arteries, and one large transverse scar near origin of left subclavian artery on arch of aorta. The scar, 1½ to 2 in. long, proximal to origin of left subclavian artery, was at a distance of 2 inches from the actual rupture, which was just distal to the origin of the left subclavian artery. There was a little tear in the intima about half an inch long with blood-stained margins. Rupture of middle and outer coats really more a leakage than an actual tear.

Remarks.

I do not think I have ever seen patients who appeared to suffer greater pain than these two. It is curious that while each of them experienced pain in the iliac fossa, the cardiac patient referred his to the right, while the man with the aortic lesion referred his to the left fossa. The latter, undoubtedly, had his most severe pain in the lower abdomen, while the former as certainly had his in the epigastric zone. It is worthy of note that the first patient, sent in as a perforated gastric ulcer, actually had a shallow ulcer in the stomach, although no peritoneal infection had occurred from it. The pain these men suffered was anginal in type, probably caused by tension in the right ventricle in the case of the necrosed perforated septum, and in the second patient by blood extravasating slowly into the periaortic tissues. I am not aware that the possibility of lesions of the great vascular organs of the thorax being mistaken for urgent abdominal emergencies has been suggested. Yet I believe it will be admitted that in both patients the clinical picture justified the assumption of some abdominal disaster. While it is recognised that a patient suffering from angina pectoris will sometimes complain of pain in the epigastric area, I believe it does not happen that rigidity of the whole abdominal wall is seen in these cases; for the fifth, sixth, and seventh dorsal nerves, which are generally supposed to be responsible for the epigastric pain, only supply a small segment of the muscles, and presumably only that portion would become fixed in such cases.

Even in relation to the subject of dissecting aneurysm I do not find any writer suggesting that abdominal pain along with rigidity of the abdominal wall might be expected to be present, and yet it is the vascular lesion which would appear pre-eminently liable to produce these symptoms. The only disease of the intrathoracic vascular organs, other than that which causes angina pectoris, that seems to be recognised as a possible cause of abdominal pain is pericarditis. Whilst MacKenzie[1] says that pericarditis is essentially a painless condition, McPhedron[2] writes that "pain may be referred to the shoulder or left scapular region but oftener in the epigastrium, where in some cases it is very severe." In the *Medical Times*, 1857, vol. ii., p. 249, there is a short note referring to a clinical lecture by Dr. Barlow, which states that "in commenting on a case under his care at Guy's he directed the attention of his class to the important indication furnished by the unduly restricted action of the diaphragm in certain cases of thoracic inflammation. He had specially noticed it in pericarditis." Wynter[3] writes that in acute pericarditis absence of abdominal movement is "as obvious as in abdominal disorders though rigidity and tenderness are for the most part absent." Cope[4] says that "Cardiac disease sometimes causes epigastric pain and vomiting, but never leads to abdominal rigidity or other signs of peritonitis."

It is, however, just the association of pain with rigidity that is so important. Epigastric pain occurring by itself may be, and often is, a trivial sign. Its significance is entirely altered when there is in addition a hard unyielding abdominal wall. Of late, writers dealing with abdominal emergencies have insisted that with perforation of a hollow organ the patient "never moves," but "lies absolutely still," &c. While this is true in the majority of cases it does not apply to all.

On March 6th, 1922, a woman with a history suggesting gastric ulcer, was admitted to hospital, stating that she wakened at 3 A.M. that day, had the desire to vomit, rose and vomited one mouthful of sour fluid, and at once experienced a feeling as if something had given way in her abdomen. This was followed by most intense pain in right side of abdomen. She was admitted to the ward eight hours later much collapsed, with face drawn and lips blue; pulse 96; temperature 99° F.; respirations 26, entirely thoracic. Blood pressure not noted. She writhed all over the bed, rubbing her hands over the belly when she was not holding on to the abdominal wall, which was absolutely rigid and hard and more so below than above the umbilicus. She continually begged for an operation for relief of her pain which was chiefly felt in the right side of the abdomen.

We were all struck by the close resemblance between the state of this patient and that of the man with the leaking aorta. The chief clinical difference between the two was that in the man hepatic dullness was present, whereas in the woman it was absent. Immediate operation was carried out and a perforation in the anterior wall of the stomach was found 2 inches below its cardiac orifice. I have on several occasions seen a patient with a perforation of stomach or duodenum behave in precisely the same manner as this woman.

THE TREATMENT OF KALA-AZAR BY "STIBENYL."

A REPORT ON TEN CASES.

BY L. E. NAPIER, M.R.C.S. ENG.,
IN CHARGE OF THE KALA-AZAR RESEARCH LABORATORY,
CALCUTTA SCHOOL OF TROPICAL MEDICINE, AND
KALA-AZAR WARD, CARMICHAEL HOSPITAL FOR
TROPICAL DISEASES, CALCUTTA.

IN 1916 Caronia[1] treated four children suffering from kala-azar with an organic compound of antimony, acetyl-para-aminophenyl-stibiate of soda. One child, evidently a very severe case, died, but the other three were apparently cured. The respective ages of the children were 3½, 2, and 1 year, and the approximate amounts of the salt that was given, 3·60, 1·0 and 0·66 g. over periods of 3 months, 16 days, and 10 days respectively. It was given intramuscularly in each case. If one accepts the suggestion that the fourth case was very advanced, and probably hopeless from the beginning, the results of the treatment with this compound were very encouraging from three points of view. First, the total amount administered was more than the amount of sodium or potassium antimony tartrate that one would care to give in the same period of time to an adult; secondly, in the second and third cases the cure was very rapidly effected; and finally, the drug could apparently be tolerated when injected into the patient's muscles.

[3] Clin. Journal, 1913, vol. xlii., p. 185.
[4] Acute Abdomen, p. 209.

In 1920 Manson-Bahr,[2] encouraged by these results, used this compound in a case of kala-azar and in a case of trypanosomiasis with good results. Messrs. Allen and Hanburys prepared this compound, and put it on the market under the name "Stibenyl." It was sold in sets of eight ampoules, each ampoule containing one dose of the compound in powder form. Doses of 0·1, 0·15, 0·2, 0·3, 0·4, 0·5, 0·6, and 0·8 g., in a freshly prepared 2 per cent. solution in distilled water, and given intravenously on alternate days, the total amount being 3·05 g., given over a period of 15 days, were advised. Acetyl-para-aminophenyl-stibiate of soda is said to contain 38·5 per cent. of antimony, which is a slightly larger proportion of antimony than either the sodium or potassium tartrate salts contain, so that, if the antimony is considered the curative factor, a total dose of 3·05 g. is well above the minimum curative dose, which by many authorities is considered to be 2 g. of sodium antimony tartrate. Trevan[3] has shown that the minimum lethal dose when given intravenously to rats is 133 mg. per kg., or eight times that of potassium antimony tartrate (16 mg. per kg.), so that the suggested dosage is well within the margin of safety.

In February, 1921, Mackie[1] pointed out that great care should be exercised in the use of this compound in the treatment of kala-azar, and mentioned the three cases treated by him in the Medical College Hospital, Calcutta, which constitute the first three cases of this series, on which I myself had done the preliminary blood and spleen puncture examinations and of which further details are given below. In May Manson-Bahr[5] wrote a letter to The Lancet saying that he also had treated a case in which 0·4 g. of stibenyl had given rise to severe symptoms, but that he still considered that the drug might prove useful in the treatment of kala-azar. In June a letter from Forsyth[6] was published in the *Indian Medical Gazette* in which he said that his experience with stibenyl had been similar to that of Mackie, and not very encouraging. In August Gatt[7] reported a case which he had treated with stibenyl and which ended fatally. This case was obviously hopeless from the beginning, but the fact that Major Gatt employed stibenyl in preference to sodium antimony tartrate shows that he was under the impression that the former was a more satisfactory form of treatment.

A Series of Cases.

As far as I know no further reports of the result of treatment with this compound have been published. A short report of my own experience may be of value to those who are interested in the treatment of leishmaniasis and other conditions in which antimony compounds are used.

Cases are given in their chronological order.

Case 1.—Major Mackie's case. Indian male aged 19. Fever on and off for one year. Spleen to umbilicus, tender palpable liver. Not markedly emaciated. Weight, 67 lb. Irregular temperature rising to 101° F. Blood: Red cells, 3,190,000; white cells, 11,618; polymorph., 9298 per c.mm. Spleen puncture: Leishman-Donovan (L.-D.) bodies found. Treatment as follows: Jan. 6th, 0·1 g. stibenyl; this was followed in about one hour by severe pain over the spleen, vomiting and diarrhœa (14 times); temp. 102°. 10th, 0·033 g.; 12th, 0·050 g.; and 14th, 0·066 g.; no obvious reaction. The patient now showed more marked lung symptoms, but was otherwise well. The treatment was discontinued in favour of treatment with sodium antimony tartrate.

Case 2.—Major Mackie's case. Indian male aged 24; fever for one year; weakness. Spleen four fingers, liver three fingers below costal margin. Emaciated. Irregular fever up to 100·5 F. Pulse-rate 100. Blood: Red cells, 4,130,000; white cells, 5040; polymorph., 2520 per c.mm. No parasites in peripheral blood. Spleen puncture: L.-D. bodies found. Treatment as follows: Jan. 6th, 0·1 g. stibenyl; this was followed by vomiting and diarrhœa (12 times), pain over spleen; temp. 101·5°. 10th, 0·033 g.; 12th, 0·05 g.; and 14th, 0·066 g.; no obvious reaction. This treatment was then discontinued in favour of treatment with sodium antimony tartrate. The patient eventually was cured.

Case 3.—Major Mackie's case. Indian male aged 16. High fever for some months. Spleen to umbilicus, liver 1½ in. below costal margin. Emaciated. Blood: Red cells, 3,400,000; white cells, 1280; polymorph., 640 per c.mm. Spleen puncture: Jan. 3rd, no L.-D. bodies found; on the 6th (pyrexial period), L.-D. bodies found, also growth of flagellates on N.N.N. medium. Treatment as follows: Jan. 10th, 0·033 g. stibenyl; and 12th, 0·050 g.; no obvious reaction. 14th, 0·066 g.; no obvious reaction, but pulse became irregular and weak, and patient died at 4 A.M. on following day. Post-mortem not permitted, but spleen and liver post-mortem puncture showed L.-D. bodies. Treatment with this compound was temporarily suspended, but a few months later, at Major Mackie's suggestion, I decided to give it another trial.

Case 4.—African native, male aged 32, who had been under treatment for kala-azar for a short time a few months previously, but after the first few injections had left hospital. His condition had relapsed, and he had now had fever for a month. He was weak and emaciated. Mitral regurgitant murmur. Spleen 3 in. below the costal margin. Blood: Total white cells, 3750 per c.mm. Spleen puncture: L.-D. bodies present. Urine: A trace of albumin. Treatment as follows: May 25th, 0·05 g. stibenyl, and 27th, 0·10 g.; no obvious reaction. 29th, 0·15 g.; no obvious reaction, except that temp. was 101° F. Blood pressure fell from 100 to 94 after the injection. 31st, patient's condition was not good, so that no injection was given. From this time onwards pulse became weaker and he eventually died on June 1st. There was no post-mortem.

Case 5.—Anglo-Indian female aged 28. Mild case. Daily fever for one month, but not sufficient to interfere with her work as a clerk. Loss of weight. Spleen 5 in. below costal margin, liver not palpable. Weight 78 lb. Blood: Total white cells, 4000. Spleen puncture: L.-D. bodies found. Treatment as follows: 2·8 g. stibenyl given in nine injections over a period of 34 days, doses being 0·05, 0·1, 0·2, 0·3, 0·4, 0·45, 0·4, 0·45 and 0·45 g. For the first four injections there was no obvious reaction; after the fifth there was a decided rise of temperature; after the sixth the patient vomited; after the seventh and eighth diarrhœa and vomiting occurred; and after the last there was severe diarrhœa and vomiting, together with collapse, which lasted for two hours. In first instances the symptoms came on two hours after the completion of the injections, but in the last two, 20 minutes and 10 minutes after. Result: Apparent cure, spleen just palpable. Spleen puncture: Direct smear and culture negative. White blood cells: 5600 per c.mm. Weight 85½ lb.

Case 6.—Indian male aged 17. Moderately severe case. Fever for six months. Emaciated, anæmic. Spleen 6 in., liver 2½ in. below costal margin. Blood: Red cells, 3,500,000; white cells, 3800; polymorph., 1558 per c.mm. Spleen puncture: L.-D. bodies numerous. Urine: Trace of albumin. Treatment as follows: Stibenyl, 3·275 g., in 12 doses, in 35 days, commencing with 0·025 g. and rising to a maximum of 0·45 g. After the sixth dose of 0·3 g., and after all subsequent doses, diarrhœa and vomiting occurred, and after the last dose the patient became collapsed. Result: Apparent cure; no fever after the last dose while in hospital (two weeks). Blood: White cells, 5750. General blood picture improved. Spleen 4 in., liver 1 in. below costal margin. Spleen puncture: Direct smear and culture negative.

Thinking that it was possible that the sample of stibenyl that we had been using might have undergone some change through having been kept for some months in a hot climate, I decided to obtain some more of this compound directly from England. I obtained one "treatment" a couple of days after its arrival in this country, and kept it in the cool incubator. This sample appeared to be the same as the previous one, except that the maximum dose advocated was only 0·6 g., as against 0·8 g. of the previous sample, and the total was only 2·25 g. instead of 3·05 g.

Case 7.—Anglo-Indian female aged 14. Moderately severe case. Eight months' fever. Treated as enteric for six months previously. Dysenteric motions for one month. Spleen 5 in. below costal margin, liver just palpable. Fever 100°–102° F. Blood: White cells, 5350 per c.mm. Spleen puncture: L.-D. bodies found. Treatment as follows: Stibenyl, 2·25 g., in 13 injections, over a period of 34 days, commencing with 0·033 and increasing to 0·3 g. No obvious reaction followed these injections. Result: No L.-D. bodies seen in spleen puncture smear, but a flagellate culture was grown from the material on N.N.N. medium. Weight increased 2 lb. Fever rising to 100° occasionally. Spleen 3 in. below costal margin. White blood count, 5600 per c.mm.

Further treatment: Potassium antimony tartrate, 17 injections, 0·64 in all over a period of seven weeks. Result: No fever for one month. Spleen just palpable, smear and culture negative. Weight increased another 12 lb.; white cells, 7500 per c.mm.

About this time Major Mackie sent me the notes of another case of kala-azar that he had attempted to treat with a sample of stibenyl that had been sent to him. I did not see this case myself. I give a few notes that Major Mackie was good enough to supply by letter.

CASE 8.—Male aged 12 years. L.-D. bodies present in the spleen puncture smear. Treatment as follows: August 15th, 1921, 0·1 g. stibenyl; no ill-effects. 17th, 0·13 g.; violent vomiting, purging, abdominal pains and giddiness commencing five hours after. 19th, 0·1 g., and 21st, 0·13 g.; no ill-effects. 23rd, 0·16 g.; more severe symptoms than after second dose, lasting 24 hours. Eventually prolapse of rectum. Symptoms commenced 15 minutes after injection. Recovery next day. This treatment was discontinued. The boy did well on sodium antimony tartrate.

Although these results were not too encouraging, I still felt that perhaps the drug had not been given a fair trial, and that if used in comparatively small doses it might still be possible to get a full course of treatment into a patient in shorter time than was possible if the simpler salts were used. I therefore obtained two more "sets" of stibenyl, and commenced to treat two more patients with it.

CASE 9.—Indian male aged 22. He was in hospital undergoing treatment for ankylostomiasis, and was accidentally found to have kala-azar by the routine performance of the "aldehyde test." The diagnosis was confirmed by spleen puncture. He gave a vague history of fever, which reacted to quinine, and also of dysentery. Thin, anæmic, spleen 5 in., liver 2½ in. below costal margin. No fever was at first obvious, but by making a two-hourly chart it was found to rise to 99° F. daily. Blood: Red cells, 3,400,000; white cells, 3270; polymorph., 1500 per c.mm. Treatment as follows: Stibenyl, 1·885 g., in nine injections, over a period of 29 days. Result: General condition seemed to be improved, but it must be remembered that he had just completed treatment for ankylostomiasis. The fever, which was almost normal before, frequently rose to 102°. The spleen was reduced an inch in size, and his weight had increased 8 lb. during his stay in hospital (seven weeks). Blood: White cells, 4370; polymorph., 1573 per c.mm. Spleen puncture: Large numbers of L.-D. bodies still present. The patient refused to stay in hospital for further treatment.

CASE 10.—Indian boy aged 13. Weight 58 lb. Fever for 4½ months. Weak, emaciated, anæmic. Cardiac dullness slightly increased, a systolic murmur at apex. Spleen 6 in., liver 2½ in. below the costal margin. Irregular fever up to 103° F. Blood: Red cells, 2,000,000; white cells, 3125; polymorph., 1375 per c.mm. Spleen puncture: Numerous L.D. bodies. Urine: Trace of albumin, no casts. Treatment as follows: Stibenyl, 1·58 g., in nine injections, over a period of 34 days, commencing with 0·035, and increasing to 0·32 g. The patient had no toxic symptoms, except occasionally pains in the epigastrium after the injections. The day after the last injection the temperature which had remained unaltered by treatment rose a little higher than usual to 103·5°, and the patient had severe pain in the epigastrium. He passed a little blood in his stool, his pulse gradually became weaker, and he died on the following morning, 40 hours after the last injection. Before his death his weight had increased 2½ lb., and his spleen had decreased by 1 in.

Post mortem: Heart dilated and flabby; no valvular lesions. Liver, fatty degeneration. Spleen large, congested, with little fibrotic change. Peritoneum had the appearance of tuberculous peritonitis (but no T.B. were found). There was a deep ulcer in the transverse colon from which there had been some hæmorrhage, but there was only a little changed blood in the large intestine. Smears from the spleen showed large number of L.-D. bodies and a growth of flagellates was obtained. Kidneys, no macroscopic change.

The results of the treatment of these two last cases I look upon as disastrous. Not only did one of the patients die in circumstances which are most unusual in a case of kala-azar, but both this patient and the other one had had an amount of stibenyl the antimony content of which was quite equal to the antimony content of the amount of the sodium or potassium tartrate salt which is considered a curative dose, and yet they were not only not cured but seemed to show the infection absolutely undiminished. The course that the disease runs is usually comparatively chronic, and the damage extensive and widespread, so that it would be absurd to expect damage which had been caused in six months to be repaired in one month, but at the same time one does expect to see the cause of the damage removed.

General Consideration of Results.

The result of the treatment, or rather attempt at treatment, of these 10 cases is not very encouraging to those who are seeking a short cut to the treatment of kala-azar. I have not tested the toxicity of the compound very thoroughly, but my experience has been that the minimum lethal dose when given intramuscularly is in the region of 150 mg. per kg., and, as I have already mentioned, Trevan found the minimum lethal dose of sodium acetyl-para-aminophenyl stibiate to be 133 mg. per kg., and that of sodium acetyl-meta-aminophenyl stibiate to be 174 per kg. given intravenously. None of the patients weighed less than 25 kg., so that no single dose that we gave was one-tenth of the minimum lethal dose (in rats). Even allowing for the debilitated condition of the patient, we were well within the margin of safety. Or, comparing it with the potassium salt, the toxicity of this is about eight times that of stibenyl, and I should have unhesitatingly given 100 mg. of the former to any of these patients. To account for this apparent discrepancy between the theoretical toxicity and the actual results in practice there are various possibilities:—

(*a*) The plasmolytic effect may be very marked, and the sudden release of protein poisons may prove too much for the patient. The symptoms in some cases were not unlike those of protein shock, but, on the other hand, there has been little in my experience to suggest that stibenyl has much plasmolytic effect.

(*b*) The cumulative effect is probably more when a compound with a large molecule is used, and some unknown factor may cause the sudden setting free of this accumulation of antimony.

(*c*) The compound may not be very stable, and may have undergone some change on its journey out to India.

Some facts were noticeable which fit in respectively with the theories just put forward. The interval between the giving of the injections and the onset of the toxic symptoms tended to decrease in each individual case; the patients acquired no tolerance to the drug, but, on the other hand, an intolerance was noticeable. Each batch of stibenyl acted in its own particular way. Cases 1, 2, 3, 4, 5, and 6 were treated with the first batch, and, with the exception of the two that died, they all had diarrhœa and vomiting, whereas Cases 7, 9, and 10, who were treated with a more recently despatched batch, did not have any symptoms like the above, but were not cured.

The pamphlet packed with each set of stibenyl states that the preparation may be used intramuscularly in children. It may, but it is very painful—much more painful, in my experience, than any of the other salts of antimony given in the same way. I am ashamed to admit that on one occasion I allowed a small amount of the solution that I was giving to leak into the subcutaneous tissues of the arm, and it gave rise to more serious necrosis than I have ever seen occur in any arm after a similar accident with the other antimony salts. Administered intramuscularly it did give rise, not to the formation of an abscess, but to severe pain at the time and a small lump which persisted for a few days. Thus, in this respect it can claim no advantage over the sodium tartrate salt.

Conclusions.

My personal experience of the use of stibenyl has been so limited (nine cases) that it would be absurd to refer to percentages of death, cure, &c., as the percentage of error in dealing with such small figures would be very great. Also I am conscious that the conclusions drawn are subject to the same chance of error, but as I am not likely to have any further experience with this compound I must use that which I have had and risk justifiable criticism.

(1) That the use of stibenyl for the treatment of kala-azar has not been successful in my hands at any rate, or in those of others in India.

(2) That there is some other factor to be taken into consideration than that of the relative toxicity of this organic compound of antimony; and that this probably also applies to other complicated organic compounds of antimony, which should therefore be used with the utmost caution.

(3) That the curative effect of an antimony compound is not in direct proportion to its antimony content.

My thanks are due to Major F. P. Mackie for permitting me to publish the notes on his cases.

Clinical and Laboratory Notes.

A NOTE ON A CASE OF ENURESIS TREATED BY ELECTRICITY.

BY MARY O'BRIEN BEADON, M.B., B.S. LOND.

(From the Victoria Hospital, Triplicane, Madras.)

THE following case shows well the excellent result which may be hoped for from electrical treatment in sphincter deficiency.

A Mahomedan girl, of about 14 years of age, was admitted to hospital on April 3rd, 1922, with incontinence of urine. The mother brought the girl up for treatment as she was always wetting herself, having done so from infancy, and there was now no prospect of her outgrowing the habit spontaneously, and her matrimonial outlook was greatly interfered with if she could not be ridded of her unpleasant condition. The typical smell of constantly dribbling urine pervaded the girl.

Condition on Examination.—We expected at first to find ectopia vesicæ, but there was no abnormality of the abdomen, but the region of the pubes was flattened, and looked almost as if the symphysis pubes were absent—i.e., as if it were a case of split pelvis. However, on rectal examination the pelvis was found normal. On inspection the clitoris was found to be absent, and the urethra was further forward than normal. The urine ran away in an almost continuous stream during examination, and there was obviously complete absence of sphincter control. The question to be decided was whether the sphincter itself was absent or whether, being present, it had never properly carried out its function. The vulva and thighs were slightly excoriated as in a case of vesico-vaginal fistula, showing that the girl suffered from habitual incontinence, and that the condition was not due to temporary paralysis, possibly due to fright.

Treatment.—Galvanic treatment was started immediately. A thin copper electrode was passed into the urethra, and the indifferent electrode was placed on the abdomen, and a current of 5 milliampères was passed for five minutes. The girl was at first much frightened of the battery, but settled down after a few days, and then she was treated with 6 to 10 milliampères for 10 minutes daily. This treatment was persisted in steadily, though at first no improvement was observed. After about 12 days' treatment a slight degree of control was established, which gradually increased. The patient had galvanic treatment for 29 consecutive days; at the end of this time there was very marked improvement, and the patient could hold her urine for a short time during the day. The galvanic current was then given on alternate days for six more treatments. She could then hold urine for three to four hours in the day, and would pass 6 to 7 oz. at a time. At night, however, she still wetted herself, so she was waked every two hours to pass water at night, and thyroid extract, gr. i. t.i.d., was given. The electrical treatment was discontinued after May 12th, and she was encouraged to hold her urine a little longer each day, till by the 23rd she could retain 10 oz. urine in the day, and no longer passed it involuntarily at night. On the 24th she was roused at night, but said she did not need to pass water, and for the first time she passed a night without wetting herself. She was discharged cured on the 29th, after nine weeks in hospital; she had been practically well for one week before discharge.

I had never had a similar case in a young person before, but I gave electrical treatment as in the above case to a woman suffering from incontinence after childbirth, the condition being apparently due to bruising of the sphincter during parturition. She recovered after about eight treatments. In applying the current reversal must be made for one to two minutes before withdrawing the electrode to avoid injury to the urethral mucosa by electrolytic action. In Lewis Jones's "Medical Electricity" it is stated: "The currents used must be decidedly painful, in order to produce a suitable impression on the nerve centres." I think it is much wiser when first treating the patient to avoid causing pain; this may involve a little longer course of treatment, but if the patient's confidence is gained at the outset, and she is not hurt, she will stand the treatment being prolonged. In inserting the electrode care must be taken not to pass it more than from three-quarters of an inch to an inch, otherwise little current will pass to the walls of the urethra. Lewis Jones considers that the best results are obtainable with the induction coil, but in my two cases only a galvanic battery was procurable, and the result in each case was good.

HERPES AND VARICELLA.

BY JOHN F. MCCLEAN, M.R.C.S. ENG.,
RESIDENT MEDICAL OFFICER, LONDON FEVER HOSPITAL, N.

IN view of recent discussion on the identity or otherwise of these two diseases this case is of interest.

A male, aged 46, was sent to the London Fever Hospital on Dec. 13th as a case of facial erysipelas. On admission he was found to have a well-marked attack of left fronto-nasal herpes, which, according to his own history, had commenced on the 5th, and subsequently become infected. There was a definite area of erysipelatous inflammation surrounding the patch of herpes and involving the left eyelid, which was very swollen. This area of inflammation continued to spread and subsequently involved the right eyelid also. Scattered over the trunk were a considerable number of vesicles, some containing clear fluid. A few more vesicles formed after admission, all eventually drying up with scab formation.

On the 23rd—i.e., 18 days after the commencement of the patient's illness—his wife wrote to inform him that their three children had that day developed "chicken-pox" and that the medical officer of health was visiting them in view of the prevalence of variola. Patient made a good recovery, but with considerable scarring over the herpetic area.

The point of interest in this case is the existence of herpes and varicella at the same time. I am indebted to Dr. C. R. Box, senior physician to the hospital, for permission to publish these notes.

A CASE OF "SUBPLEURAL" LIPOMA IN A CHILD.

BY C. F. BEYERS, M.B., B.S. LOND., F.R.C.S. ENG.,
SURGICAL REGISTRAR, JOHANNESBURG HOSPITAL.

THE occurrence of a lipoma arising in the anterior mediastinum of a child is so rare that the following case seems worth recording.

A European boy, aged 22 months, had a swelling on the front of his chest, first noticed by his mother when he was 10 months old. It was painless and caused no symptoms, but grew steadily larger. On examination the child appeared to be rather pale, but was sturdily built and otherwise quite healthy. To the left of the sternum, and overlying the fifth, sixth, and seventh costal cartilages was a soft, clearly defined swelling, measuring roughly 2 inches. in all directions. Its surface was somewhat lobulated, and it gave a feeling of fluctuation. It had no connexion with the skin, but was firmly fixed to the subjacent tissues. I made a diagnosis of cold abscess arising from a tuberculous rib.

Operation.—I made an incision parallel with the sixth rib and cartilage and found a fatty pedunculated mass, the pedicle of which appeared to pass through the sixth interchondral space into the thoracic cavity. I removed the sixth and seventh cartilages, which appeared normal, and traced the pedicle to a second fatty mass, slightly smaller than the extra-thoracic portion. It occupied the anterior mediastinum, pushing the pleuræ away from each other and resting on the pericardium. It was clearly circumscribed, lying quite loose in the areolar tissue and having no obvious organic connexion with either pleura or pericardium. In removing the tumour, which shelled out quite easily, I had to tie two fair-sized arteries which ran down vertically on each side of the isthmus; these were probably the terminal branches of the internal mammary artery. The skin wound was closed and the patient made an uneventful recovery. The pathological report on the specimen stated that it was a fatty tumour.

The points of interest in this case are: (1) The very youthful age of the patient; (2) the dumb-bell or collar-stud shape of the tumour; (3) its origin and site. It is difficult to say definitely from what structure the lipoma arose. It may equally well have originated in the extra-pleural or extra-pericardial fat, or in the loose areolar tissue which fills the anterior mediastinum, or even from the connective tissue between the slips of the triangularis sterni muscle. Bland-Sutton uses the expression "subpleural" and refers to a similar case described by C. Gussenbauer, where the extra-thoracic portion of the tumour appeared underneath the pectoralis major and simulated a sarcoma. Ewing in "Neoplastic Diseases" mentions similar cases described by Cruveilhier and Conner, together with a case of Czerny where the tumour appeared externally in the back. How can a soft tumour such as a lipoma penetrate the chest wall through an extremely narrow interchondral space, guarded by slips of triangularis sterni muscle and occupied by intercostal muscle and membrane? Possibly the increase in size and vigour of the heart may have assisted in its extrusion, though one would expect that it would take a line of lesser resistance and grow laterally, prolapsing into one or other pleural sac—a circumstance which does occur, according to Rokitansky (see Bland-Sutton's "Tumours, Innocent and Malignant").

ACUTE OSTEOMYELITIS TREATED BY EARLY INCISION; RECOVERY.

By P. B. Kittel, B.Ch. Camb., M.R.C.S. Eng.,
SENIOR HOUSE SURGEON, METROPOLITAN HOSPITAL, LONDON, E.

The following is an account of early incision performed in a case of acute osteomyelitis, near its onset.

On August 8th, 1922, the patient, a male aged 8, was brought to this hospital complaining of headache and inability to walk from pain in his left leg. He stated that on the previous evening he had experienced pain in his left thigh, felt ill, and vomited. Unable to sleep during the night, he was brought to hospital the next day. There was no history of injury to the left leg.

Condition on Admission.—The patient appeared to be in pain, was flushed, and held his left leg flexed slightly. His left thigh was exquisitely tender to pressure on the bone about its middle. It measured 1¼ in. greater in circumference than the right thigh. The tibia on the left side was not tender, but there was slight œdema over the lowest third. Temperature 103·8° F., pulse 136. There were no signs of inflammatory disease in any other part of the body.

Operation.—The condition was diagnosed as acute osteomyelitis, and it was decided to incise the periosteum of the left femur forthwith. The operation was performed under a general anæsthetic. The periosteum was exposed over a length of about 2 in. on the lateral side of the limb at the level of the highest third through a skin incision about 4½ in. long. The periosteum was incised, and separated from the bone for about ⅛ in. each side of this incision with a periosteal elevator. There was no collection of any sort found outside or under the periosteum. The bone appeared congested. A rubber tube was inserted through the incision to the bone, the skin was closed with fishing gut sutures. Two hours after the operation the temperature fell to 99° and the pulse to 108. The patient was asleep and in a perspiration. The next day the temperature was 102° and the pulse was 98. For the next two weeks the temperature ranged from 98·4° to 99° and the pulse slowly fell. The tube was removed on the second day and the stitches on the tenth day. The wound healed by first intention.

The boy left the hospital in good health at the end of one month from the time of admission.

I am indebted to Mr. H. Curtis for permission to publish this case.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ANÆSTHETICS.

Cardio-Vascular Conditions in Relation to Anæsthesia.

At a meeting of this section of the Royal Society of Medicine on Feb. 2nd this subject was fully debated. The chair was occupied by the section President, Dr. A. L. **Flemming** (Bristol).

Dr. J. **Strickland Goodall** introduced the subject from the standpoint of a preliminary examination of the patient in a systematic manner. When this had been done and the result imparted to the anæsthetist, the latter was the person best able to decide as to what was the best anæsthetic for that particular case. He had often been impressed by the casual way in which, in an operation case, the anæsthesia side was regarded. In some instances great care was taken over the choice of a surgeon, but almost any anæsthetist was considered good enough. And sometimes a physician gave an opinion as to whether a case was suitable for an anæsthetic to be administered without knowing or inquiring what was the nature or the probable duration of the proposed operation. In setting out the scheme of examination of cardio-vascular cases he was aware that in some there could only be a superficial examination owing to the condition of the patient. The object of the examination was to minimise the operative risk. He thought that before long every general hospital in London would have a properly equipped cardiological department, run by properly trained specialists, who would examine every case intended for operation, instead of by inadequately trained assistant physicians. The examination of the cardio-vascular system could be considered under the following three heads: (1) examination of the heart; (2) of the vaso-motor and vascular systems; (3) of the respiratory pump. And it was advisable, wherever possible, to examine with the patient standing, prone, and half reclining. Inspection at once revealed the typical mitral face, the pale face of aortic disease, the pale yellowish face of infective endocarditis, and the very pallid face of pericarditis. If there was cyanosis one examined the jugulars and looked for clubbing of fingers, inspected the carotids, felt for the liver and spleen, and looked for œdema of legs. Also attention would be directed to the apex beat; was it diffuse or heaving? It was often possible to detect at once, before the patient entered the operating theatre, whether mitral stenosis, auricular fibrillation, excessive venous engorgement, and an enlarged liver were present.

With regard to palpation, if there were a slapping apex beat it meant that the muscle of the ventricle was not contracting rhythmically. This might be because: 1. The muscle was degenerated; it was one of the first signs of myocardial degeneration. 2. Because it was poisoned. 3. Because it was not sufficiently stretched by adequate filling. A heaving apex beat meant left ventricular hypertrophy. A dual apex beat mostly meant the existence of a double lesion, generally mitral. In addition to examining the liver and the spleen, one should try to ascertain whether there were râles in the lung. Special care should be devoted to the character of the first sound, for it indicated the condition of the muscle and of the auriculo-ventricular valve. The sound was shortened in any condition which interfered with the contractility of the ventricle. He believed that a systolic murmur at the apex always meant a leakage through the mitral valve. An accentuated aortic sound meant a high peripheral resistance and a raised blood pressure. If it were ringing in character it meant damage to the structure of the aortic valve, and usually dilatation of the aorta above it. It did not mean a high peripheral resistance. The quality of the first sound at the apex gave the best information as to the condition of the myocardium. When the latter was in question, the electro-cardiograph should always be used. Exercise was one of the most reliable methods of assessing the condition of the myocardium. When the normal heart was exercised it gradually sped up, the blood pressure rose, respirations increased in frequency, then there was a return to normal. Some hearts were unduly accelerated by exercise and the return to normal was very tardy. In a third type there was impaired acceleration on exercise, and heart-block and flutter ensued. A fourth type, met with only in athletes, was that in which exercise doubled the rate. Exercise might also vary the rhythm, and if irregularity of the heart beat ensued, it was due either to extrasystoles (indicating fatigue) or auricular fibrillation (damage to auricular muscle) or alternation. Exercise might also alter the normal heart sounds.

In aortic regurgitation the diastolic murmur should be examined for over the aortic base, over the midsternal line, and to the pulmonary side. The cases with the worst hearts, from the anæsthetic standpoint, were those having profound myocardial toxæmia; those with marked hyper-irritability; those having a definite degeneration of myocardium; and those in which that structure was acutely inflamed. In aortic cases the vaso-motor mechanism must also be carefully investigated. In aortic regurgitation the systolic blood pressure was high, and the diastolic low; also, the pressure in the arm was higher than that in the leg, the difference in the two being supposed to indicate the vaso-motor tone.

Though he had for some years been examining about 300 heart cases per week, including many thyroid cases, he had not been consulted in regard to an anæsthetic in 2 per cent. of his cases. In thyroid cases the two chief kinds of heart were the pneumo-mechanical and the toxic heart met with in Graves's disease. He had found that in the thyroid cases submitted to operation the blood pressure rose after the operation; also that in typical Graves's disease the blood pressure passed through three phases: an initial rise, followed by a 10 per cent. to 20 per cent. drop, then a further rise. If operation were done after the first rise, the blood pressure rose, and this was the stage at which the patient was in trouble or difficulty. In this disease the heart underwent a progressive degeneration; tachycardia occurred first, resulting in some myocardial fatigue, followed by atonia and leaking of different valves, and later pericardial friction rubs, and toxic myocarditis. The cause of death in these cases was, he considered, ventricular fibrillation, showing myocardial damage. It was fairly safe to operate on cases of Graves's disease if the ventricular myocardium was sound and the blood pressure was not very high at first. For these the best general anæsthetic was open ether; the worst, chloroform. In the pneumo-mechanical heart the myocardium was not degenerated, therefore operation was safe.

Sir BERNARD SPILSBURY said that in the summer of 1913 he analysed all the fatalities which at that time he had investigated—namely, 104 cases—in which death occurred either during the administration of the anæsthetic, or within a very short time of it. These did not include cases of delayed chloroform poisoning. In the cases of the kind since 1913 he could point to two differences. The 104 cases to 1913 were those in which he made the post-mortem examination himself; and they represented at least 100,000 administrations. In 58 of the 104 chloroform alone had been employed; chloroform mixed with ether, or A.C.E. in another 22, the two aggregating almost 80 per cent. of the fatal cases. Of pure ether there were only 12 cases, and stovaine only one case in that series. He divided the fatalities into two groups: The first consisted of a small class, 32 in number, in which death was associated with status lymphaticus. One-fourth of these occurred in the first five years of life. The changes characteristic of lymphatism he had fully corroborated since—viz., the presence of a functional thymus gland, or of some thymus tissue overgrowth in the lymphoid apparatus. A less constant change which he found in the cases of status lymphaticus was either fatty degeneration or brown atrophy of the heart muscle. Recently he had classified the degeneration of heart muscle into two kinds; the diffuse, fine type, never very advanced, but much more uniform. This was the condition so frequently present in status lymphaticus. The other kind was more gross and patchy.

The second great group were the deaths which occurred in connexion with malignant growths generally. Cases of Graves's disease presented a very important group, also such other desperate conditions as acute peritonitis and intestinal obstruction. The status lymphaticus cases did not exceed 33 per cent. of the total; in a larger proportion there was either fatty degeneration or brown atrophy. In many cases there was present a grave bodily condition which endangered life, quite apart from the administration of the anæsthetic, so that the latter played only a minor part in the fatal issue. In the last nine years he had investigated 174 fatalities, and analysis showed a definite drop (i.e., to one-half) in the proportion of status lymphaticus cases—i.e., only 26 of the 174. One-third of the cases were in the first five years of life. In this later series there was a larger proportion of cases in which the anæsthetic probably had no direct part in the death; he referred to such conditions as pulmonary embolism, air embolism, very serious uterine hæmorrhage, the opening of an aneurysm, &c. There were also many cases in which the patient was moribund when brought; in these latter stovaine had been given in 12. This was employed because the patients were desperately ill, and it was considered the safest of the anæsthetics. In the 174 cases, pure chloroform was given in 56, chloroform with some other substance in 56, ether alone in 36, stovaine alone in 9, and nitrous oxide in 17. The administration of chloroform had greatly diminished recently, and that of ether was much increased. Chloroform Sir Bernard Spilsbury considered a most dangerous anæsthetic in cases having myocardial degeneration. In this second series of 174 cases he had systematically examined the heart muscle, and in nearly all he found either fatty degeneration or brown atrophy, or a combination of the two. He spoke of four deaths in the series due to anæsthetics taken for the purpose of murder or suicide, in all of which except that of a boy aged 11, one of the conditions of heart muscle referred to was found. Only a small proportion of the 174 cases showed advanced valvular disease.

Dr. GOODMAN LEVY agreed that subjects of valvular disease took the anæsthetic well, especially chloroform. Ventricular fibrillation was less likely to occur when the general blood pressure was low. When syncope occurred in a person with fatty heart, it did not necessarily follow it was because of the fatty degeneration. Great care should be exercised in cases of heart-block—i.e., a complete dissociation of the auricular from the ventricular beat; chloroform might so accentuate this condition as to lead to collapse. Subjects of Graves's disease were liable to die suddenly without an anæsthetic.

The PRESIDENT said a matter on which the anæsthetist required help was when a patient went to a heart specialist who told her she perhaps had aortic regurgitation and that an operation could be safely submitted to provided the anæsthetic was stovaine; or as she had exophthalmic goitre the anæsthetic must be pure chloroform. This opinion should not be given to the patient, but to the anæsthetist.

Dr. JOHN PARKINSON said the profession was greatly in need of a rapid heart stimulant: strychnine, camphor, ether, alcohol, caffein had very little action on the heart. He urged the necessity of submitting patients suffering from auricular fibrillation to a few days' preparation before the operation; this would greatly diminish the operation risk.

Mr. **James Berry** said he operated largely on a class of case—thyroid cases—which had exceptionally bad hearts, and he was indebted to Dr. Strickland Goodall for much valuable help. The report of the electro-cardiographist was of very great value to the operating surgeon. There should certainly be a closer coöperation between cardiologist, surgeon, and anæsthetist. Each case must be judged on its own merits. Two classes of case always gave him anxiety, the fat, flabby person, and the patient with advanced malignant disease, especially if the glands were cancerous.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

A meeting of this Society was held on Feb. 2nd, when an address on Some Recent Work on Colour Blindness was given by Mr. R. A. **Houston**, D.Sc., lecturer on physical optics in the University of Glasgow. In the course of his address Dr. Houston said that during the past eight years statistical surveys of the colour vision of more than 2000 students have been made at Glasgow University. They have already been described in papers in the Proceedings of the Royal Societies of London and Edinburgh and in the *Philosophical Magazine*, and the present lecture dealt with some of the principal results obtained. Frequency curves were shown representing the variation of the ability to discriminate colour about a mean. These demonstrated that normal variation covers almost everything as regards women, but not as regards men. The colour blind could not be regarded as an extreme case of normal variation. Trichromasy passed into monochromasy directly and not through dichromasy as an intermediate stage, as the original form of the Young-Helmholtz theory required, and the results of the investigation rendered untenable the latter theory and also the Hering theory. The final theory when it came would be a photochemical one, and the prospects of advance were at present hopeful.

CARDIFF MEDICAL SOCIETY.

A meeting of this Society was held on Jan. 16th, Prof. **Ewen J. Maclean**, the President, being in the chair.

Dr. **H. A. Haig** gave a lantern demonstration of the cytology of tumours, illustrated, in addition, by numerous sections. The points of the differential diagnosis of benign, borderland, and malignant growths were presented. He further showed examples illustrating the presence of nucleolar fragments in the cytoplasm of mitosing cells in malignant tumours, a phenomenon confined to cancerous and sarcomatous growths.

Dr. J. W. **Tudor Thomas** described a case of

Endothelioma of the Orbit

in a young woman of 27, who said that something had been wrong with the right eye since childhood, and that during the last two years the eye had become pushed forward. She complained of diplopia and occasional pain in the eye. On examination there was found to be about half an inch of proptosis of the right eye, and displacement downwards considerably below the level of the other eye. There was no paralysis of muscles, but movement of the eye upwards was restricted. Under the upper lid was felt a hard mass, somewhat nodular and tender, and firmly fixed to the roof of the orbit. It protruded slightly beyond the upper orbital margin. The fundus was normal. A diagnosis was made of orbital tumour, probably a fibro-sarcoma. Seven months ago the tumour was removed through an incision in the line of the eyebrow. It was firmly attached to the roof of the orbit, and appeared to be growing from the orbital periosteum, and it extended well behind the eye. The tumour was about the size and shape of a small pigeon's egg, and on microscopic examination was diagnosed as an endothelioma. The patient now had no diplopia, the eye gave her no trouble; it had returned to its normal place in the orbit, and was practically similar in appearance to the other eye.

Mr. **D. J. Harries** read a paper on the

Influence of Intestinal Bacteria upon the Thyroid Gland.

He drew attention to the discovery that thyroxin was a derivative of tryptophan, an amino-acid normally produced in the intestine during digestion of proteins. The normal flora of the human intestine could be divided into two main groups: (1) fermentative, (2) putrefactive. In lower animals it was possible to destroy the putrefactive group by administering carbohydrates, especially lactose and dextrin, but unfortunately this was not possible in a healthy human being. In a series of experiments on guinea-pigs A. Distaso and Harries had shown that the presence of indican in the urine depended on the presence of putrefactive organisms in the intestine, and that the disappearance of the latter coincided with the disappearance, not only of the indican, but of all the organic sulphates from the urine. This was important, as it explained the sympathetic symptoms in exophthalmic goitre. In another series of experiments the speaker had shown that in exophthalmic goitre the indican and other organic sulphates in the urine diminished as the symptoms increased, and that they ultimately disappeared in serious cases, and only reappeared during recovery from the disease. In ordinary parenchymatous goitre there was no diminution, but often an excess of indican and all organic sulphates. In these cases any diminution in the indican suggested the onset of exophthalmic symptoms. Parry Morgan's recent work on patients agreed with the results obtained by Distaso in lower animals. He found very few colonies of putrefactive organisms on media inoculated with fæces from exophthalmic goitre cases. Partial thyroidectomy in exophthalmic goitre reduced the symptoms by diminishing the size of the gland, and therefore its capacity for manufacturing thyroxin from the tryptophan absorbed; and that the amount of tryptophan absorbed depended, naturally, on the food taken and on the amount converted into indol and skatol by the putrefactive organisms in the intestine. Therefore diet was important. The prognostic value of the urine examination for indican was also emphasised, as its absence in early cases of exophthalmic goitre was of grave significance. The methods for re-establishing a putrefactive flora in exophthalmic goitre were dealt with, and the suggestion was put forward that the difficulties encountered might be due to a temporary immunity against the particular group required. The following general conclusions were drawn:—

1. Exophthalmic goitre is due to the excessive absorption of tryptophan from the intestine; this in turn is traceable to the absence of the indol producers from the intestine.
2. The absence of indican from the urine indicates the absence of indol producers from the intestine.
3. In exophthalmic goitre the early disappearance of indican from the urine is of serious prognostic importance.
4. Operative treatment has a definite place in the treatment of exophthalmic goitre. Medically, much can be done by suitable dietetic measures.
5. Diffuse parenchymatous goitre is characterised by an excess of indican in the urine, suggesting an excessive destruction of tryptophan. If this excess gives place to a diminution or complete disappearance of indican, that suggests that the case is assuming the exophthalmic form.
6. Myxœdema is due to atrophic changes in the thyroid gland, which loses its capacity for dealing with the circulating tryptophan, whether that substance be excessive, deficient, or normal in amount. The disease is thus compatible with the presence or absence of urinary indican.

Dr. **Prichard** mentioned a case of exophthalmic goitre which improved very much after an attack of acute rheumatism.

The **President** mentioned the possible connexion between eclampsia and intestinal bacteria, and drew attention to the good results obtained by intestinal lavage.

Dr. **Parry Morgan** mentioned the feasibility of influencing the flora by administering the required organisms in keratin capsules by the mouth.

Mr. HARRIES, in reply, stated that Dr. Prichard had opened up the subject of the interaction of various groups of organisms the one on the other. In all probability the infection in his case had interfered with the dominance of the fermentative group, allowing the putrefactive to be re-established. Colonic lavage in eclampsia acted in two ways: First, dilution of the toxins by the water absorbed; secondly, removal of large numbers of organisms from the large and lower part of the small intestine. Dr. Parry Morgan's suggestion had already been considered and was going to be adopted. In conclusion, Mr. Harries stated that the action of one ductless gland on the others had been much overestimated. When it was realised that the putrefactive group of organisms controlled not only the supply of tryptophan to the thyroid, but also the supply of thyroxin (from which adrenalin is probably produced) to the suprarenal, it was unnecessary to assume any interaction in exophthalmic goitre. He had avoided discussing any of the other ductless glands as he wished to keep as far as possible to the gland under discussion—viz., the thyroid.

Reviews and Notices of Books.

PREVENTIVE MEDICINE.

An Introduction to the Practice of Preventive Medicine. By J. G. FITZGERALD, M.D., Professor of Hygiene and Preventive Medicine and Director of the Connaught Antitoxin Laboratories of the University of Toronto. Assisted by P. GILLESPIE, M.Sc., and H. M. LANCASTER, B.Sc. Also Special Chapters by other Contributors. London: Henry Kimpton and Co., Ltd. 1923. Pp. 826. 37*s.* 6*d.*

THIS important new work is the most ambitious Canadian text-book hitherto issued on the subject of preventive medicine and gives high promise of future achievements. The subjects dealt with are those usually included in manuals of hygiene and public health, with a few omissions such as climate and soil; an unusually large space is given to the prevention of communicable diseases. What may be described as the non-medical chapters are concerned with water, milk, and foods (by Mr. H. Lancaster), with a section on domestic and community sanitation by Mr. P. Gillespie, and one on air and ventilation by Mr. Lancaster. The 48 pages on water deal with many aspects of this subject. There is, however, little or no information on the epidemiological aspects of water-supplies, and bacteriological examination is scarcely stressed adequately as compared with chemical examination. From this point of view Mr. Lancaster's chapter on milk is more satisfactory. The practice as to preservatives in milk is closely similar to that in this country, all preservatives being prohibited except boric acid in cream, the presence of which must be declared, and not in excess of 1 part in 400. Apparently the English distinction between dairy cream and grocer's cream is not made. In Ontario there appears to be only one grade of certified milk, which, among other requirements, must be milk derived from cows who fail to react to the tuberculin test to which they are submitted every six months. It is stated that "extensive observations on infants fed on pasteurised milk show that there is a possibility of scurvy developing in some cases." This is scarcely in accordance with European experience and one would like to examine the evidence. But the warning is useful as emphasising the possible risk of renewed domestic boiling of pasteurised milk.

The chapter on diet by Dr. A. Hunter gives a fairly complete summary of our knowledge of this subject. Reference is made to the demonstrated potency of the therapeutic administration of sodium iodide in limiting the prevalence of goitre among school-children in the Great Lake Basin of North America, an observation too little known in this country. We note that recent observations showing the importance of sunlight as well as of cod-liver oil in the prevention of rickets are not included in the review of this subject. To domestic and community sanitation 76 pages are devoted. This section is well illustrated, and contains much useful information; but we should have preferred to exchange much of it for fuller information on the agencies more closely associated with preventive medicine. The time when the health officer can hope to be also a sanitary engineer has passed; and he must perforce be content to understand thoroughly the principles of structural sanitation, leaving the details of construction to his engineering colleague. In the chapter on air and ventilation, while due prominence is given to the importance of circulation of air, it is pointed out that, though air circulation in circumstances of crowding greatly increases comfort, it tends to promote the dissemination of disease-producing bacteria ejected by sneezing and coughing. When such possibilities of infection exist, fans increase the risks of overcrowding.

The special medical part of the book occupies over 300 pages, wherein the chief communicable diseases and the means for preventing them are well discussed. The chapter on tuberculosis is perhaps the least satisfactory. The long extract from the report of a board of consultants in Canada on tuberculosis in the Canadian expeditionary forces in the war shows only that the official figures and the comparisons with figures for American and British troops are untrustworthy. The statistics given in this and in other diagrams are not well selected, and some of them are redundant. On p. 199 a table is given from McVail showing the reduction in the deaths from small-pox in England during a series of years. Unfortunately this is described as a reduction in the "fatality" of small-pox, this word in epidemiological literature being usually restricted to mean "case-mortality." In the small-pox chapter there is an interesting contrast between the view associated with the name of Dr. C. K. Millard and the older teaching that vaccination should be universally enforced. It is agreed that vaccination protects the individual against small-pox, but in the older communities it cannot in practice be enforced without consent, and the vaccination of contacts and collateral measures have succeeded in limiting local outbreaks so far. On the other hand, Dr. Heiser's experience is quoted as showing that in the Philippines general vaccination has almost eliminated small-pox. In communities of relatively low civilisation it would appear that universal vaccination is the most effective and most easily arranged safeguard; but in well-organised communities, given complete public health administration, and all that this implies, protection against small-pox may be obtained by prompt emergency vaccination. Although in this volume it is noted that the practice of not undertaking terminal disinfection in diseases like scarlet fever is increasing, the evidence adduced by C. V. Chapin and others in favour of this relaxation is not given, and a large amount of space is devoted to the details of disinfection.

Three most important chapters deal with maternal and infant mortality, school hygiene, and public health clinics. From these chapters the student and medical practitioner will gain a clear idea of the possibilities of preventive medicine, though here again the statistics are not very well selected or arranged. The chapters on vital statistics and on public health organisation cover the usual subjects. There is a useful table on p. 672 giving the health appropriation per capita in a large number of American States and the relative share taken by different branches of public health work. Mention must be made of the admirable first chapter discussing the aims and problems of preventive medicine. While insisting that much already is being done, Dr. Fitzgerald looks to the dawn of the day when the private physician will be engaged to keep his patient well by routine examination, by supervision, and advice. He advocates medical, nursing, and dental supervision of the whole of life, on the lines on which free education is now provided at the public expense. Many will not take advantage of it, but there should be no excuse for neglect of means for the retention or the restoration of health.

Der Künstliche Pneumothorax.

By Ludwig von Muralt. Second edition, with a Supplement: Kritische Erörterung und Weitere Erfahrungen. By Prof. Karl Ernst Ranke. Berlin. Julius Springer. 1922. With 53 illustrations. Pp. 150. 10*s.*

Only about two-thirds of this book on artificial pneumothorax are written by the late Ludwig von Muralt. The last third is written by Dr. Ranke, professor of medicine at the University of Munich. In his foreword he gives a short obituary notice of his collaborator. Ludwig von Muralt was infected by tuberculosis when, as a student, he was carrying out a post-mortem examination. Thenceforth his life was a constant battle with tuberculosis. A mathematician of no mean order, he brought to the study of medicine a certain precision and logical reasoning, evidence of which is abundant in the present work. Beautifully illustrated, it gives a comprehensive survey of the subject, from its history to the results achieved.

The author is quite right in giving to Saugman the credit for introducing the manometer into the operation, converting it into a technically efficient and exact procedure. Both the puncture and the open method of Brauer are described. Realising the great dangers and difficulties of the first injection, when the pleural surfaces are in apposition, the author recommends the open method to those physicians who have not mastered the delicate technique of the puncture method. For this class of physician it is better that he inflicts on the patient the discomforts of the open method than that he should cause death by gas embolism. It is admitted, however, that most of the published deaths from gas embolism occurred during refills and not at a first injection. With regard to the comparative importance of gas embolism and pleural reflex as causes of death, the author favours the present general tendency to interpret nearly all the fatalities as sequels to embolism. He does not, however, dismiss pleural reflex as a mere phantom of the imagination. He has obtained good results in 48 of his 70 cases. Prof. Ranke's contribution to this book is of a supplementary and editorial character. One of his most interesting tables shows how greatly different authorities vary with regard to the frequency with which the induction of a pneumothorax was prevented by pleural adhesions. At the one end of the scale, Harms failed to induce a pneumothorax in only 5·9 per cent. At the other end, Saugman failed in 35 per cent. Prof. Ranke calculates that the experience of these two and four other authorities shows that in 27·1 per cent. of all cases it is impossible to induce a pneumothorax.

This book is a valuable addition to the large and rapidly growing literature of artificial pneumothorax.

Psycho-Analysis.

Introductory Lectures on Psycho-analysis. By Prof. Sigm. Freud, M.D., LL.D., Vienna. Authorised English translation by Joan Riviere. With a Preface by Ernest Jones, M.D. London: George Allen and Unwin. 1922. Pp. 395. 18*s.*

Freud's own work has hitherto appeared in a form which, whilst providing a record of the growth of his theory, was disconnected and gave no general view. His "Psycho-pathology of Every-day Life" and "Interpretation of Dreams" are complete in themselves and will probably become land-marks in the development of a theory that has hitherto survived an opposition as determined as any in the history of science; but the general exposition of psycho-analysis has been in the hands of other writers whose competence was not always equal to the efficient performance of the task. In these lectures, delivered in 1915–17, Freud fills the gap.

In the first part he talks of the psychology of errors, and gently leads up to the idea that they are not accidental and meaningless, but have a meaning which may be detected by the perpetrator, though more often there are mental processes involved of which he is ignorant. Part II. is devoted to dreams; ancient and modern views are sketched, and the author admits that physical stimuli, to which importance has been attached as a sufficient explanation, may be the occasion of the dream, but can no more explain its whole content than the occasion of the writing of *Macbeth* (the accession of James I. explains the whole content of that drama. He lays down the propositions that dreams are a mental process and that a man can possess knowledge without knowing that he does; these he sets out to prove, and he leads up to free association by proposing that to obtain the meaning of the dream we should ask the dreamer. In describing the censorship he defends himself against the charge that psycho-analysts can only see the evil side of human nature: "We dwell upon the evil in human beings with the greater emphasis only because others deny it, thereby making the mental life of mankind not, indeed, better, but incomprehensible" (p. 123). Free association is sharply distinguished from the interpretation of symbols by the analyst. Free association gives the dreamer's interpretation and suffices in many dreams, but there occur "silent" elements where association fails, and the substitution of meanings by the analyst leads to a satisfactory explanation of the whole dream, which would otherwise remain meaningless and disconnected. This is the most disputed part of psycho-analytical theory, especially as the symbols interpreted pertain largely to the sexual life; this symbolism has been described and attacked so often that it is not necessary to give an account of it here. Freud supports it by appeal to recognised symbolism of similar nature in mythology, philology, folk-lore, and religion, but this appeal is not so convincing as the results of free association. The third and last part of the book treats of the neuroses, with their pathology and therapy. If Freud's classification be accepted, apart from his ætiology, it will almost remove from medical literature the word "neurasthenia," which now means so many things that it has nearly lost all meaning. The psychoneuroses comprise conversion hysteria, anxiety-hysteria, and the obsessional neurosis; the actual neuroses are anxiety-neurosis, neurasthenia (the word being used in a narrow sense), and hypochondria, and these, which are the direct somatic result of sexual disturbance, yield nothing towards the study of psycho-analysis. This grouping of the psycho-neuroses accords with clinical experience, though the frequent combination of the anxiety-neurosis with anxiety-hysteria would obscure the distinction between them, even if this distinction were generally accepted.

Freud's well-known views on resistance, infantile sexuality, and the repression of sexual impulses lead to the newer and more difficult theory of the libido and the possibility of its being transformed into anxiety or withdrawn from an object to return to the ego—that is, to the sum of the instincts which are not sexual, and is in conflict with them. Although he speaks of the libido as energy Freud does not fall into the error of supposing that he knows what that energy is, but warns us in this connexion that "The edifice of psycho-analytic doctrine which we have erected is in reality but a superstructure, which will have to be set on its organic foundation at some time or other; but this foundation is still unknown to us" (p. 325). It is to be noted that, contrary to a usual assumption, Freud expressly states (p. 366) that paranoiacs, melancholics, and those suffering from dementia præcox are unaffected by psycho-analytic treatment; even some of his followers may be surprised to read concerning war cases and others: "The traumatic neuroses are not fundamentally the same as those which occur spontaneously, which we investigate analytically and are accustomed to treat; neither have we been successful so far in correlating them with our views on other subjects; later on I hope to show you where this limitation lies" (p. 232).

Freud's handling of the opposition is on the whole tolerant. He tries to understand the difficulties of those who find his theories repugnant and impossible of acceptance, and recommends the study of one's own personality as a means of obtaining the conviction of the reality of the processes which psycho-analysis describes. In his last chapter he shows resentment, perhaps justifiable, in describing cases which were unfairly used to demonstrate "the unfortunate results of treatment." His marshalling of facts and deductions, the full statement of the arguments of the other side, and the recognition of doubts and of gaps in accounting for the phenomena met with, embody the results of years of hard and earnest work. In view of the intense opposition to his theories, a destructive scientific criticism of this book ought to be forthcoming; no serious critic of psycho-analysis should omit to read it and no serious student can afford to neglect it.

We are told in the preface that an American translation of this book has already appeared but that, owing to its defects, it was decided to do the work anew. Mrs. Riviere has given a smoothly-running version, but her own statement, in a book dealing with the psychology of errors, that the customary sense of "unconscious" is "absence of unawareness" (p. 94, footnote) calls for a full analysis in the next edition.

Remembering and Forgetting. By T. H. PEAR, M.A., B.Sc., Professor of Psychology in the University of Manchester. London: Methuen and Co. 1922. Pp. 242. 7*s.* 6*d.*

THIS book had its origin in a course of lectures to R.A.M.C. officers at the Maghull training centre. Prof. Pear contrasts the earlier investigations into memory, which carefully excluded meaning from the material studied, with the present methods that find memory to depend largely upon emotional values. The psycho-analytical view of the relation of dreams to memories is illustrated by an analysis of a dream of the author, who shows that certain observations raise the question whether we forget anything in the sense that it really passes beyond recall; he discusses the belief that all forgetting is due to repression and leaves open the question. There is little of the abstruse in the book, which forms a good introduction to many of the principles of modern psychology and makes the subject one of human interest.

MISTAKES AND ACCIDENTS OF SURGERY.

By HAROLD BURROWS, C.B.E., M.B., B.S., F.R.C.S., Assistant Surgeon, Royal Hospital, Portsmouth; Hunterian Professor, Royal College of Surgeons. London: Baillière, Tindall and Cox. 1923. Pp. 470. 10*s.* 6*d.*

NO power on earth can banish from surgery the accidents dependent upon the frailties of human nature, any more than these can be eliminated from military tactics, engineering or political activities, where an error of judgment may result not in the loss of a single life but in deaths which are counted in scores, or even thousands. It is remarkable how few accidents or mistakes occur in surgery, especially in the surgery performed in hospitals to which a medical school is attached, though the surgeon frequently operates under conditions of stress, suggestion, and fatigue, which are conducive to inaccuracy in mental and physical processes. In these large hospitals the undergraduate student is a most critical onlooker and is not reticent over his opinions, so that a mistake can scarcely occur without the whole staff hearing about it. These incidents are rare.

The author of this book appears to be excessively conscientious in attributing to surgery certain accidents which have only the remotest possible connexion with the art, such as fracture of the skull from falling off the operating table after a tonsillotomy, or the removal of the wrong leg. Other mistakes he relates are almost inconceivable in their stupidity or clumsiness. All one can say about such performances as the division of the body of the penis instead of the cord in a varicocele operation; the removal of piles without making a digital rectal examination, a malignant growth being present; the performance of a colostomy in a collapsed colon for obstruction in the small gut; the suture of the lower ileum to the stomach in gastro-jejunostomy; the enema incident on p. 89, and the remarks of the surgeon who mistook the iliac artery for the appendix—all that it is possible to say is that the operators were untrained and mentally unfitted for their work.

Against most of the ordinarily possible mistakes mentioned the student is warned in the usual textbooks he reads. There is much sound advice scattered through the volume and also some doubtful teaching. So eager is the author to tell of mistakes, that twice (p. 39 and p. 64) he relates rumours of an accident which he has not seen or even been able to verify by conversation with other surgeons or in the literature! Mr. Burrows has an easy, fascinating method of presenting his subject; we cannot help wishing that such powers of expression had been devoted to a subject of less questionable value. One may well ask why a whole book should be devoted to the mistakes and accidents of surgery, and after careful consideration, be still unable to see what useful purpose is served thereby. It is perfectly clear, on a perusal of the volume under consideration, that the author had in view only one very laudable object—to call the attention of the inexperienced or occasional surgeon to the pitfalls of his craft, and to prevent a repetition of the errors which have occurred in the past. Whether his aim will be accomplished, and, on the final count, whether good will result, is a matter of opinion.

BRONCHOSCOPY AND ESOPHAGOSCOPY.

A Manual of Peroral Endoscopy and Laryngeal Surgery. By CHEVALIER JACKSON, M.D., F.A.C.S., Professor of Laryngology, Jefferson Medical College, Philadelphia, &c. London and Philadelphia: W. B. Saunders Company. 1922. Pp. 346. 27*s.* 6*d.*

DIRECT examination of the upper air- and food-passages by means of electrically lighted tubes is one of the most notable examples of the adaptation of modern science to medicine, and has already been the means of saving a large number of lives. Prof. Chevalier Jackson is eminent among the pioneers in this work and, being in charge of a bronchoscopic clinic, has had a remarkable experience in the treatment of patients by these methods. Any work from his pen will therefore be read with grave attention.

The first chapter of the book, which is an abstract of the author's larger work, entitled "Peroral Endoscopy and Laryngeal Surgery," gives a good description of the instruments used; only the endoscopes designed by Prof. Jackson, with distal illumination, are described, and no mention is made of other patterns or of the proximal lighting largely used in Europe. In the second chapter the special anatomy of the parts concerned is discussed, together with a useful series of measurements. The following chapters deal with the technique of the preparation of the patient and of the introduction of instruments. It is noteworthy that general anæsthesia is never used in Prof. Jackson's bronchoscopic clinic, and he maintains that a dyspnœic patient should never be given a general anæsthetic. Children at the clinic receive neither local nor general anæsthesia, nor sedative, for laryngoscopic operations or œsophagoscopy, and the same rule applies to œsophagoscopy in adults; but for laryngeal operations in adults and for bronchoscopy in adults and older children a preliminary injection of morphine and atropine is given. It is pointed out that the œsophagus itself is without sensation, but in œsophagoscopy it is considered safer for the beginner to secure relaxation by ether anæsthesia. Prof. Jackson is highly experienced and is accustomed to work with the aid of a team of four well-trained assistants; but it is difficult to see how the average laryngologist, who is but an "occasional bronchoscopist," is to extract a foreign body from the bronchus of a frightened child without the aid of any anæsthetic or sedative. Practice on dogs doped with morphine is highly recommended, but the procedure is not possible in this country.

A large part of the book is occupied by an excellent description of the symptoms produced by foreign bodies and of the technique of their removal. The discussion of the diseases of the œsophagus is also excellent; it might, indeed, have been expanded, particularly the description of achalasia, or "diaphragmatic pinchcock stenosis" (to use the author's term), at the expense of the chapters on laryngeal diseases, or tracheotomy, subjects not strictly appropriate to a work on endoscopy. The volume gives the impression of being the rather hasty writing of a busy man; misprints are frequent and include a phrase about "the treatment of radium by cancer," while the author is unduly fond of such clumsily-coined words as "autodrownage." These defects will not prevent it from being of great use to all laryngologists. The illustrations are excellent.

LE CURETTAGE UTÉRIN.

By J. FIOLLE, Professeur à l'École de Médecine de Marseille, Chirurgien des Hôpitaux. Paris: Masson et Cie. 1922. Pp. 128. Fr.8.

IF the very simplicity of the operation of curettage of the uterus had not tended to make it one of the most abused operations in gynæcology, it would hardly have seemed necessary to write even a brochure of some 128 pages on its indications and technique. However, though when carried out in suitable cases it is a most satisfactory procedure, it is by no means free from possible risk and is occasionally uncertain and disappointing in its results. The author has, therefore, done the profession a service in placing before them clearly and succinctly the indications for this operation, its technique, the accidents which may occur, and its results. The conclusions he draws are such as most experienced gynæcologists would agree with, and they would also be in complete accord with the note of warning he utters as to the abuse of this simple and, under suitable conditions, safe procedure.

DIFFERENTIALDIAGNOSE.

By Dr. RICHARD C. CABOT, Professor der klinischen Medizin an der Medizinischen Klinik der Harvard-Universität, Boston. Zweite Auflage nach der 12. Auflage des Originals. Von Dr. H. ZIESCHÉ, Leitender Arzt der Inneren Abteilung des Josef-Krankenhauses zu Breslau. Erster Band. Berlin: Julius Springer. 1922. Pp. 603. 15s.

THE appearance of a second German edition of Prof. Cabot's well-known book shows how this interesting method of clinical teaching appeals to European students. As the author said in his original preface: The attempt to make and defend a differential diagnosis brings all one's failings into sharp relief—and, we may add, adds piquancy to a systematic treatise. Dr. Ziesché, who is responsible for an admirable translation, tells us that the first German edition was sold out within six months. In his preface he goes through the list of standard students' text-books of medicine on the continent, pointing out how they differ from Cabot's conception. Using the author's name for that of the book, as students do, he tells us that Matthes, which now takes the place of Leube on special diagnosis, is more of a systematic introduction to clinical examination. Ortner, which brings together a mass of observations based upon remarkable wealth of clinical experience, is used principally as a work of reference. Cabot's work will, Ziesché thinks, lead to clinical thinking among the many young practitioners whose education fell in the difficult years of war and who thus lost their opportunity of prolonged apprenticeship as assistants. Rudolf Schmidt's "Clinic of Gastric and Intestinal Disorders" comes, for one region of the body, nearer to Cabot's method. In preparing the second edition, Ziesché acknowledges his indebtedness to other text-books, especially to French's "Index of Differential Diagnosis." A translation of the remaining volume of Cabot is foreshadowed. While the original will naturally appeal most to English students, we can heartily recommend Ziesché's translation as a means of acquiring facility in reading medical German.

PELVIC NEOPLASMS.

By FRANK WORTHINGTON LYNCH, A.B., M.D., Professor of Gynæcology and Obstetrics, University of California; and ALICE F. MAXWELL, B.S., M.D., Instructor of Gynæcology and Obstetrics, University of California. London and New York: D. Appleton and Co. 1922. Pp. 432. £1 1s.

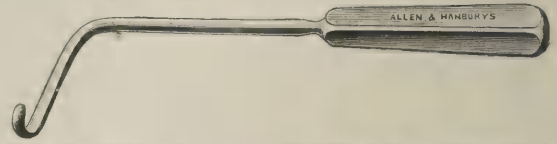
IN this monograph the authors have considered pelvic neoplasms from the historical, histological, and clinical aspects; particular attention has been devoted to the various methods of recognising malignant growth and the results of the most modern methods of treatment—operative, radium, and X rays. Much space is devoted to this question and the conclusions come to are of much value. The authors consider in detail the results in cases of operable carcinoma of the cervix treated with radium, of border-line cases, of inoperable cases, and of those in which there has been a recurrence. In apparently inoperable cases, first treated with radium and then operated upon, the great difficulty often experienced from the fibrous induration resulting is drawn attention to; the experience is almost universal, and for that reason the advice given to operate upon these cases within ten days of the application of the radium should be followed. No doubt the ideal method of dealing with cases of malignant disease at the present day is the preliminary use of radium in all, even early operable cases, the free removal of the growth by the most extensive operation available, and the subsequent treatment of the patient with radium or X rays as a prophylactic measure. More details of the after-results of such cases are, however, required before we can come to definite conclusions on this difficult problem.

The authors have carried out their task thoroughly. They give information about all the varieties of benign and malignant tumours met with in the pelvis, whose value is added to by a good index and a number of excellent illustrations. The series of monographs, of which this particular work is one of the most useful, is a credit to the authors and to the publishers, and will enhance the reputation of the American school of gynæcologists and obstetricians.

New Inventions.

ELEVATOR FOR THE FIRST RIB.

THIS instrument, a modification of the ordinary Doyen's curved rib elevator, is designed for removing the first rib in extensive thoracoplasty in order to collapse a phthisical lung. It differs from the ordinary Doyen elevator in having the hook-shaped end very short and narrow to correspond with the ribbon-like shape of the first rib. The hook is set at a lateral twist to the shaft and two inches below the line of the shank.



The instrument is made by Messrs. Allen and Hanburys, Limited, Wigmore-street, London, W.

W. H. C. ROMANIS, M.C. Camb., F.R.C.S.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 10, 1923.

THE HEALTH INSURANCE CONFERENCE.

The recent conference of representatives of all the various groups of executive officers, working under the National Insurance Acts, marks an important step forward in the development of the insurance service. It was, as we noted last week, a plenary conference in the sense that for the first time since the first Act came into force in 1911, officials from the approved societies and members of insurance committees have met representative chemists and doctors in free debate. No wonder two days were not found sufficient in which to thrash out the burning questions which agitate the workers; a brief note on some of these appears on p. 301. But it was good for protagonists to meet face to face and to repeat, if they chose, the severe criticisms with which they have been associated in the columns of the daily press. Certain critics, no doubt wisely, did not accept the invitation sent out by the Insurance Acts Committee of the British Medical Association. As each item on the agenda paper was taken in succession it became more and more obvious that the subjects were too big to discuss satisfactorily in a large conference, and it was decided that a small standing committee should be formed to come to real grips with the urgent questions between the professional and administrative sides of the conference. There is material for many meetings of such a committee, and we hope that the magnitude of the task will not deter public-spirited men on both sides from going on until a solution is found to all the difficulties impeding the smooth working of a great national service.

The immediate need is for better mutual understanding. In a recent appeal case at the Ministry of Health the report of the finding of the court contains the dictum: "The practitioner is entitled to expect the patient's coöperation." This gives a clue to the solution of many of the difficulties in insurance work. Coöperation is essential in the proper working of the scheme, and to secure it there must be confidence and goodwill, which are themselves unobtainable without understanding. The ignorance and stupidity of the insured person was referred to on more than one occasion, and he was not there to defend himself. That he is ignorant is not to be wondered at, for he has few means of learning the intricacies of national insurance. His stupidity is the natural outcome of the darkness in which he is left. His agent makes demands upon him which he is unable to comprehend; the most accessible friend is his panel doctor, who often goes far beyond his own sphere in his interest for the welfare of his patient. We are glad to see a suggestion to make a serious attempt to educate the insured person. Sir William Glyn Jones stated that the Association of Insurance Committees had prepared a model lesson for school-leavers upon the privileges and duties of health insurance.

But the insured person is not the only element requiring education. The medical profession has not been wholly enthusiastic in working the Act, and some may still regard their duties lightly and be apt to perform them in a perfunctory manner. But complaints under this head are becoming more and more a thing of the past. Enthusiasm for the service is needed on both sides, and the approved society respresentatives should realise the debt they owe to the practitioners who have loyally worked the Act under immense difficulties and in the face of grave opposition. We doubt whether the insurance service will attract enough medical men of the highest standing until it is developed and made more complete. Sir Thomas Neill, who led the discussion on efficiency, was reluctant to consider extensions of the service until what is at present provided is done well. It seems difficult to explain to the non-medical mind that the whole of medical work is interdependent, that general practitioner service must be supplemented by consultant and specialist services and by hospital provision. It is clear enough to the doctors that much of the prolonged sickness which worries the societies at present might be cut short if prompt hospital treatment were afforded and the necessary additional investigations provided. The well-worn phrase "team-work" was many times on the lips of one or another at the Guildhall Conference, but the phrase rightly covers not only concerted work amongst local practitioners—such as the formation of a rota to cope with urgent calls—but a grand combination in which hospital surgeons and physicians and laboratory investigators all coöperate as they did in the medical organisation of the Navy, Army, and Air Force during the war.

◆

UNDIAGNOSED ABDOMINAL EMERGENCIES.

Two cases of emergency where the source of the trouble appeared to be in the abdomen and was discovered to be in the thorax are described in our present issue by Mr. J. Hogarth Pringle. No better instances could be given of the difficulty surrounding the question whether or no to open the abdomen when the exact diagnosis is not clear. Every surgeon will be in agreement with the premises and conclusions of Prof. C. A. Morton in his article (p. 298) on the Treatment of Abdominal Injuries. In these cases, where a clear history of injury is to be obtained—an injury consistent with some serious abdominal damage—and above all in cases where there is a penetrating wound, no time should be lost in subjecting the patient to a thorough exploration under the best possible conditions. Occasionally the urgency may be so great that appropriate arrangements for hospital or nursing home cannot be made, and in these circumstances the best must be made of an emergency theatre. Every effort should be exerted to obtain conditions for operating as perfect as possible, since the extent of the injury is unknown. It must never be forgotten that the operation required may be one of the greatest magnitude, calculated to tax the surgeon and his assistants to the utmost.

The general practitioner, though with good surgical experience, may be placed in a dilemma by a sudden call to a case of abdominal injury. He may be forced into immediate interference by one of those syndromes so clearly described by Prof. Morton, knowing that conditions may be present which are beyond his competence to deal with. Such risks have to be taken, and when no more skilled help is available, are rightly taken. The position in an abdominal crisis without history of accident is, however, very different, and the duty of the practitioner is to be much more cautious of surgery. In cases of injury, an exploratory laparotomy, even if it reveal no gross injury, is much more pardonable than a similar performance when no injury has occurred. Opening the abdomen in the absence of clear-cut symptoms, or without a very certain comprehension of what may be required, has, we are told, become the fashion. Even though the operation of exploration terminates solely with the removal of an appendix, scarcely abnormal, this operation is hardly beneficial, while if more is attempted in the way of short circuiting it may be definitely harmful. Abdominal exploration in the hands of the most careful and perfect surgeons is followed in a large number of cases by adhesions which may be crippling, and if the surgeon is careless of asepsis the results may, indeed, be deplorable. Maltreatment of an injured limb cries aloud for redress, but the unfortunate viscus anchored, twisted, or anastomosed incorrectly is a hidden and inarticulate plaintiff in the action for damages. If the results of imperfect surgical procedures in the abdomen were as obvious to the surgeon as are the results of imperfect treatment where the eyes or limbs are in question, he might be somewhat more restrained in his activities. The practical surgeon should not only have a sound idea as to when to open the abdomen, but a still clearer notion as to when to get out of the excursion without inflicting damage. The safest principle to adopt is manifestly courage in the presence of an accidental injury and caution in its absence.

THE BACTERIUM PNEUMOSINTES.

The "discovery of the germ of influenza" by Olitsky and Gates, of the Rockefeller Institute, has been widely announced. The work of these investigators has been noticed in our columns on several occasions and, as our readers are aware, is concerned with the demonstration that a filter-passing, living organism, just within the limits of microscopic visibility, is the real causal agent of this disease. Such a conception of influenza did not originate with these authors, but has probably developed from the contention of Kruse in 1914, that the common cold is due to such an organism, an opinion which was extended by the same worker to influenza during the pandemic of 1918. About the same time Nicolle and Lebailly, in France, put forward a similar opinion, whilst the work carried out by two independent sets of collaborators in the British Army is well known. The researches of Gibson, Bowman, and Connor, which were published in the thirty-sixth special report of the Medical Research Council, led them to claim that lesions comparable with those of human influenza could be produced in animals by the intranasal and subconjunctival inoculation of blood and sputum from patients suffering from the disease. They also claimed to have cultivated the virus by the Noguchi technique. This research makes rather confused reading and was interfered with by the unfortunate death of Gibson from influenza. Then the changes in organisation consequent upon the armistice caused it to be brought to a rather premature conclusion; consequently, though extremely suggestive, this work cannot be considered to have been carried out with that rigour of control which is necessary for scientific proof. Nothing has been more destructive to the filtrable-virus theory in this country than the work of Rose Bradford, Bashford, and Wilson, who claimed to have cultivated a filtrable organism from a number of conditions, influenza amongst them. These cultures were submitted to Arkwright, at the Lister Institute, who found many of them to contain other than filtrable organisms and, accordingly, the research was held to have failed.

The work of Olitsky and Gates, whatever may be the judgment ultimately passed upon it, owes much as regards its inception to previous researches. The first results of the American investigators were published in 1920,[1] and since then numerous other papers have been published by them, especially in the *Journal of Experimental Medicine*, dealing with various aspects of the problem. Briefly, they claim to have cultivated from the human disease a minute cocco-bacillary body, which they have named *Bacterium pneumosintes*, and to have produced in animals with such cultures lesions comparable to the disease in the human subject and identical with those produced in animals of the same species by the naso-pharyngeal washings from cases of acute epidemic influenza. They conclude that this organism, which is capable of passing Berkefeld filters, is the true cause of influenza. Now the first essential in any investigation appears to be the limitation of efforts to elucidate the problem to cases of epidemic influenza. From the clinical side we are faced by a great difficulty. Are epidemic and sporadic influenza identical infections? If not then we must admit that various infections can occasion the same syndrome and the problem becomes very complicated. This possibility seems more remote in the case of the epidemic disease, and for this reason we realise that one of the weightiest arguments advanced against the claims of Pfeiffer's bacillus to be the causal agent is its variability. Morphologically, biologically, and serologically this organism is divisible into such a number of types that it seems highly improbable that it can be the unique cause of an epidemic disease whose characters, at all events in fixed periods of the epidemic, are so constant. In Olitsky and Gates's work the material appears to have been well chosen. The basis of their investigation has been the selection of a suitable animal for their experimental work and the finding of a criterion of infection. Animals in general seem singularly resistant to the influenza virus, and this fact has proved a great difficulty in most previous work. The monkey has been chiefly used, but the Rockefeller investigators have found the rabbit more suitable. On the intra-tracheal injection of sputum, crude or filtered, these animals did not develop a fatal illness, but it was found that a rise of temperature and a pronounced leucopænia were indicative of the presence of an infection which, when the animal was killed, showed itself by an œdematous and congested condition of the lungs with patches of hæmorrhagic pneumonia. These experiments were originally planned with the object of producing lesions in the animals which would contain the causal organism, and it was hoped that by successive passages from animal to animal contaminatory organisms, usually present in the sputum, would be eliminated, and the true infecting agent finally survive alone. This expectation appears to have been realised. It further having been proved that the virus causal of these rabbit lesions was filtrable, cultural experiments were proceeded with. By a modified Noguchi technique positive cultures were obtained both from the filtered sputum of human cases and from the lung lesions of experimental rabbits; such cultures, on reinjection, proved capable of reproducing the condition in other rabbits. Further, by agglutination and immunity tests different strains of the organism have been shown to behave similarly, and, moreover, it has been found that on recovery the infected rabbits are immune from infection by material from another source.

---

[1] Journal of the American Medical Association, No. 74, p. 1497, May, 1920.

This, though brief, is a fair summary of the work under consideration. There are many side issues of the greatest interest, but also more important considerations in the main theme which call for further comment. Recently MERVYN GORDON, in this country, has confirmed these findings in so far as they refer to the occurrence of a culturable filter-passing microbe in the nasal secretions of influenza patients. And last week the November issue of the *South African Medical Record* reached this country containing an account of the minute organism isolated by Sir SPENCER LISTER on Noguchi medium from pharyngeal washings of influenza patients. The difficulty is one of technique which at present is extremely crude. We might picture, as an analogous situation, a bacteriologist, deprived of the higher powers of the microscope, attempting a bacteriological analysis of infected organic material, such as sputum or fæces, after filtering off visible particles by an ordinary paper filter. Growth there would certainly be upon media inoculated with the filtrate, but in the circumstances it would be extremely difficult to discern exactly what this consisted of, and it would be even more difficult to attempt any correlation between such a culture and a specific disease. We have a somewhat similar position with filtrable viruses obtained from contaminated materials. It is to be presumed that there are many organisms, both saprophytic and pathogenic, of this class, and we readily call to mind the existence in sputum of the encephalitic and keratogenic viruses recently described in this situation, especially by LEVADITI, whilst the American workers themselves have met with growths which they conclude are not the *Bacterium pneumosintes*. The immunological experiments of OLITSKY and GATES suggest that their organism is growing in pure culture. We note, with curiosity, that amongst their control experiments they cultivated the nasal secretions of eight persons suffering from acute coryza and obtained no growth whatever, thus completely failing to confirm KRUSE'S findings.

As regards the significance of the organism in human influenza, we may conclude from the quoted work of the Rockefeller investigators, and GORDON'S confirmation, that the first of KOCH'S postulates has been practically fulfilled. The successful cultivation and sub-cultivation of the organism in like manner fulfils the second of these, whilst the reproduction of the disease by such growths fulfils the third, so far as it concerns the disease in the rabbit. The full proof of the relationship of the rabbit lesion to the human subject appears still to be lacking. In strict justice what we can regard as completely proven is that there is a living virus in the nasal secretions of human influenza cases, which is pathogenic for rabbits, and which, when injected intra-tracheally, is capable of producing influenzal-like lesions. Sir SPENCER LISTER produced a typical attack of uncomplicated influenza in one of nineteen human volunteers whose nose and throat were sprayed with the second generation of a culture from his filter-passing organism. The full demonstration of KOCH'S third postulate is always difficult and here it is that the claims of Pfeiffer's bacillus have halted. Sometimes such proof is provided by accident, but more often it is inferred from the appearance, in the patient's serum, of antibodies towards the suspected organism. This line of proof has not yet been explored, but it is in this direction that in the future we must look for a final conclusion as to the meaning of OLITSKY and GATES'S original and admirable investigations.

Annotations.

"Ne quid nimis."

THE CONSTANCY OF THE GERM-PLASM.

AT a time when deplorable housing conditions at home and threatening starvation abroad are causing anxiety for the health of the rising generation, it is some consolation to have our attention recalled to the constancy of the germ-plasm. Weismann may have been wrong in his description of the mechanism, but his conception of continuity has undoubtedly been fruitful in the region of social medicine. It is a recurrent marvel how from generation to generation Nature reasserts herself and provides the raw materials for full and perfect growth from the most unlikely sources. Many examples are given in the Tenth Study in National Deterioration,[1] where Miss M. N. Karn and Prof. Karl Pearson address themselves to the question, what factors in heredity or environment influence the general health of babies. The evil effects of imperfect clothing, of bad feeding, of improper habits on the young of the human species have, they suggest, been deduced hitherto by some instinctive process from observational experience. These deductions have never been statistically tested, and the resources of the Eugenics Laboratory of University College, London, have now been called in to analyse the records of data provided by a baby clinic in a large manufacturing town.

The material consisted of 20,000 or more sheets of questions filled in by the voluntary workers at the clinic. There is a horrible habit among the women in poorer urban districts of using a rubber teat as a baby pacifier; this object is apt to fall into the gutter, or at least into the bottom of a dirty perambulator, when it is restored to the baby's mouth, sometimes with a rub on a dirty apron, sometimes without. Great stress has been laid on the evil results which follow. The Eugenics Laboratory is unable from the figures available to trace any marked influence on the child's health. Judged by these, the pacifier is a better indication of what a baby's health has been than what it is; mothers in bad health are apt to use the nearest means to their hand of keeping their babies quiet. Statistically, the implement is more closely related to the health of the mother than to the health of the baby. The authors turn their attention to the alleged evil of artificial feeding. From the available data they learn that the difference of health between breast-fed and artificially-fed infants is not great when the health and habits of their parents are good. It is the parents of bad health and of bad habits who weight the death and delicacy rates of the artificially-fed babies. These are the deductions that can be made when the material provided by a number of partially-trained field workers is treated without impressionism and without prejudgment. Similar analysis of the more weighty material to be obtained from investigations under medical control is promised, and it remains to be seen whether it will overthrow the accumulating evidence of the infant's ability to weather the storms of early environment. A striking illustration from the other end of life of the constancy of the germ-plasm is given by Prof. Raymond Pearl in a recent monograph on experimental biology.[2] The habit of old age in a family appears to be incorrigibly ingrained. Pearl cites A. G. Bell's study of the Hyde genealogy, and constructs a table showing the influence of longevity in both the father and mother upon the expectation of life of the offspring. Put into words the table shows 20 years added to the average life of a group of people through having extremely long-lived parents instead of parents dying under the age of 60.

[1] Study of the Data provided by a Baby Clinic in a Large Manufacturing Town. By Mary Noel Karn and Karl Pearson, F.R.S. Department of Applied Statistics, University of London. Drapers' Company Research Memoir. Cambridge University Press. 1922. Pp. 128. 15*s*.

[2] The Biology of Death. Being a Series of Lectures delivered at the Lowell Institute in Boston. By Raymond Pearl, the Johns Hopkins University. London and Philadelphia: J. B. Lippincott Company. 1922. Pp. 276. 10*s*. 6*d*.

Father's age at death.	Mother's age at death.		
	Under 60.	60–80.	Over 80.
Under 60	32·8	33·4	36·3
60–80	35·8	38·0	45·0
Over 80	42·3	45·5	52·7

Pearl adds that a careful selection of parents in respect of longevity is the most reliable form of personal life insurance. So far, all this is to the social good. Biologic law is working continuously towards safeguarding the race.

In another way the persistence of biologic law may turn out to be an evil in the highly developed social community. The relative fragility of boy babies has long been a matter of comment. The large excess of male births is over-compensated by the death of boy babies to the extent that, from school life on, girls are more numerous. The tendency is not local or particular. Boys die in larger proportion than girls at every age, in every country, and from every disease, with the single exception of whooping-cough, the excessive mortality varying from 20 to 40 per cent. Dr. F. E. Wynne, whose prize essay on this subject appears in the February issue of *National Health*, suggests that there is some intrinsic quality in maleness that impairs the hold on life of the male organism as compared with the female, and he traces the diminished survival rate of the male back to a time when fewer males were required for impregnation and when it was biologically desirable that only those most potent to maintain and improve the race should survive. The remarkable exception in the case of whooping-cough, which is much less fatal to male than female children, suggests to Dr. Wynne that the katabolic male responds better to the demand for violent expulsive effort. The disorder is to the boy a form of furious sport and the fact contains the hint to free the growing limbs of male children from artificial restriction and afford full opportunity for natural exercise. What success will attend an effort to neutralise an inborn character can hardly be foreseen.

BILHARZIASIS IN EUROPE.

THE important fact made known by Borges[1] in 1921 that bilharziasis was, and had probably been for some time, endemic in Portugal is one that must have given cause for no little concern. At any rate, the matter was considered of sufficient importance to warrant a special scientific inquiry. The results of this inquiry, conducted jointly by Bettencourt and Borges of the Instituto Camara Pestana, Lisbon, have recently been published in an interesting and comprehensive report.[2] The first case reported on by Borges was a woman of Tavira (Algarve), who had never been out of the locality. The source of infection was found to be the public washing pool, supplied by water from a spring, which while not exactly hot was found to have a temperature of about 80° F. Moreover, the pool proved to be a habitat of a species of mollusc, *Planorbis corneus metidjensis*, constituting a suitable intermediate host for the larval bilharzias. Conditions being thus suitable it is not surprising that several cases of infection were discovered. With few exceptions these were women who were in the habit, barefooted, of washing clothes in the pool. About 70 per cent. of such women were discovered to be infected with bilharzia. Only one male case was recorded, a boy of 13, who was in the habit of bathing in the pool. According to Bettencourt and Borges, the infection was probably introduced from Morocco, and while it seems fairly certain that this endemic focus has been in existence for some time the infection does not appear to have spread to any extent, probably because suitable local conditions are not common. It has on occasion been asserted that bilharziasis is endemic in Greece, but according to Prof. Savas, of Athens, such cases as have been discovered have contracted the disease in Egypt. Since the late war sporadic cases of bilharziasis have become known by personal experience to a certain number of medical men in this country, but such cases have in every instance, we believe, been contracted abroad. On general grounds it might be asserted that the disease is quite unlikely to become endemic in any part of this country. One must not forget, however, that 30 years or so ago a similar assertion might have been made, with a certain show of reason, in the case of ankylostoma, which, however, invaded the Cornish tin mines and created quite a considerable amount of trouble. On that account sanitarians in this country cannot afford to ignore the possibility, remote though it be, of the occurrence of indigenous bilharziasis.

THE LIST OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

THE list of the Fellows, Members, and Licentiates of the Royal College of Physicians of London for the year 1922 has just been issued. It contains the names of 370 Fellows and 600 Members, 50 of whom were admitted or re-admitted to membership during 1922. The number of Licentiates of the College on Jan. 1st, 1923, was 14,448. The number of diplomates in special subjects is now becoming considerable, being 1030 for public health, 371 for tropical medicine and hygiene, 64 for ophthalmic medicine and surgery, and 34 for psychological medicine. The classified country list is of interest; the only counties in England now devoid of Fellows or Members are Cumberland, Durham, Lincoln, and Monmouth. Twelve Fellows or Members give addresses on the Continent of Europe. The statement of receipts and payments of the College for the year ending Sept. 29th, 1922, which is bound up with the list, shows a revenue from admission fees of Fellows and Members amounting to £2083, from investments £839, from trust funds £1395, and from examination fees under the conjoint scheme (for five quarters) £10,015. During the year a sum of £6049 was invested without substantially reducing the balance at bank.

THE RESULTS OF TONSILLECTOMY.

SINCE tonsillectomy has become a local anæsthesia operation it has gained much ground. Is its present popularity justified? So little has hitherto been published with regard to the permanent effects of tonsillectomy on adults that it is well to give publicity to data on which the practitioner can form a comparatively independent opinion. The material must be large, the procedure uniform, and the interval between the operation and the date of re-examination must be considerable if these data are to be instructive. It is also necessary that adults and children should be classified separately, as they differ materially in this respect. These conditions have been fulfilled in a paper recently published by Dr. F. Norsk in *Ugeskrift for Læger* for Dec. 7th, 1922. He addressed an elaborate questionnaire to 229 adults (70 men and 159 women) who had undergone tonsillectomy in the ten-year period 1910–19 in a hospital in Copenhagen. The technique of the operation was uniform, and the surgeon who performed the operations also checked the late effects. Of the 130 patients who answered the questionnaire, 72 also presented themselves for re-examination. Of the 102 operated on for recurrent attacks of acute tonsillitis, 85 had lost their symptoms, and 9 had obtained some relief. Of the 33 operated on for peritonsillar abscess, 30 had lost their symptoms and 2 were better. All the 14 patients who had suffered from acute tonsillitis with rheumatic fever were symptom-free, and so were all the four whose chronic rheumatism had been an indication for tonsillectomy. There were also five cases in which the operation had been performed for tonsillitis with fœtor oris, and only in one case did this symptom persist. An instructive discovery made on re-examination of 72 patients was that the proportion of successes was greatest in the cases in which a clean sweep of all the tonsillar structures had been made. The question is often asked: May tonsillectomy prove actually injurious as well as failing to relieve the symptoms for which it is undertaken? Unfortunately, the answer cannot be emphatically in the negative. In one of Norsk's cases tonsillectomy stirred a latent infection into activity, the operation being followed by a severe septic disease involving the joints and heart and crippling the patient for several years. Some 40 of Norsk's patients wrote complaining of symptoms suggestive of pharyngitis; it is conceivable that this condition may have existed before the operation, having been masked by the more troublesome symptoms associated with the inflammation of the tonsils. It is certainly significant that atrophic pharyngitis was not found in any of the 72 re-examined patients. Three wrote that their capacity for singing had been impaired, and Dr. Norsk is evidently well advised in not recommending tonsillectomy for professional singers if the operation can possibly be avoided.

CHEMICAL CONSTITUTION AND BACTERICIDAL ACTION.

The recent Mann Lecture at the Royal Society of Arts was devoted to a popular exposition on the Relation between Chemical Constitution and Antiseptic Action in the Coal Tar Dyes, by Mr. T. H. Fairbrother, M.Sc., and Dr. Arnold Renshaw, both of Manchester, who have devoted much time and attention to the subject. Sir Humphry Rolleston, who presided, pointed out the important nature of the work both from a national and economic aspect, and also from its scientific and medical interest. The aniline dyes originally discovered by Sir William Perkin in 1856 had before the war passed almost entirely into the hands of chemical manufacturers in Germany, and it is probable that this was largely due to the comparatively slight financial encouragement given to chemists working on these lines in this country, which contrasted with the wise action of Germany in this matter. Our overwhelming handicap in this respect became obvious early in the war, and it might be hoped that in spite of difficulties this would be permanently remedied by organisations in this country. Sir Humphry Rolleston went on to remark how fascinating from a chemical point of view had become the problem of difference in action due to alteration in structure of a synthetic body; the amount of skilled labour devoted to this problem was well shown by the names "606" and "914" applied to preparations eventually found, after the number of trials indicated, to be suitable by Ehrlich in his epoch-making research on the chemotherapy of syphilis. In the "seventies" the work of Pasteur and Koch had established the specificity of disease—namely, that an infectious disease was due to one kind of germ and to that alone; later it became known that after each infectious disease specific antibodies peculiar to the disease and preventing its recurrence appeared in the patient's blood. The conception of the production of specific drugs which should, when introduced into the body of a patient, kill the parasite (parasitotropic) and not hurt the organs (or be organotropic) of the individual was due to Ehrlich. Before the war Sir Almroth Wright and others, working on the effect of "optochin" on pneumococcic infections, had attacked the same problem, insisting that the bactericidal drug should be monotropic or have a selective affinity for one germ only. This was not quite the same as the recent view that groups of allied mono-organisms were similarly acted upon by the same chemical agent. Sir Humphry Rolleston spoke of the happy combination of two workers: Mr. Fairbrother being a chemist with a brilliant record of work in the war, and now attached to the British Dye-Stuffs Corporation; Dr. Renshaw, a physician-bacteriologist, able to judge of the staining and antiseptic action exerted on micro-organisms by the dyes that his chemical colleague provided. It was by such team-work that real advances in our knowledge were likely to be obtained. Before the war it had been suggested, especially by J. W. Churchman in America, that some relation would probably be found between the power of a given dye to stain a special bacterium or protozoon on the one hand and its power to inhibit their growth or kill them, and during the war much use had been made of aniline dyes as antiseptics, such as acriflavine, malachite green, brilliant green, and rosaniline. The lecturers were able to give some information on these points, and an abstract of that part of the lecture which dealt with selective action on micro-organisms appears on p. 314 of the present issue.

ROYAL SOCIETY OF MEDICINE: THE POSITION OF ASSOCIATES.

We learn, and we own it is with some surprise, that the new class of Associates in the Royal Society of Medicine has attracted as yet small support. Associates are qualified men or women, British or otherwise, who within five years of their first professional qualification apply to the Council for election as non-corporate Associates of the Society. They cannot vote or take any part in the management of the Society, but, if elected by the Council, they are entitled to all the ordinary privileges of Fellows, with the exception that they do not receive the Proceedings gratis, and their use of the library is limited. They pay no admission fee but only the annual subscription of 3 guineas, payable on Oct. 1st of each year, and after having paid three annual subscriptions an Associate, if elected to the Fellowship, is exempt from paying the admission fee. Associateship terminates automatically on Sept. 30th following the expiration of five years from the date of the Associate's first professional qualification.

Special forms of application can be obtained from the Secretary of the Society, and we commend the scheme to the notice of our readers, as an excellent way of keeping in touch with modern developments of medicine.

TREATMENT OF RECTAL PROLAPSE IN CHILDREN.

The vast majority of cases of prolapse of the rectum in children can be cured without resort to surgical measures, but those who have had extensive experience recognise that in a few children conservative treatment is unsatisfactory; even when it is eventually successful the treatment may have to be prolonged, the general health suffering from the effects of the rectal catarrh set up and perpetuated by the prolapse. Various suggestions have been made for the relief of such cases. Prof. Rudolf Eden, of Freiburg,[1] reports 10 cases successfully treated with injections of "humanol," a preparation of oil derived from human fat.[2] He injects 30–80 c.cm. of the oil in such a way that it forms a submucosal wall around the anal canal, extending upwards for a distance of 3–4 cm.—i.e., above the sphincters—having previously reduced the prolapse. He states that the immediate effect is mechanical owing to the presence of the oil, but that from the day following the injection the sphincter is found to be contracted, even in those cases where it had been markedly relaxed before the operation. Absorption of the oil takes place slowly, and when complete the mucosa remains firmly fixed to the underlying tissues, which themselves show no tendency to prolapse. This effect is probably due to a mild inflammation in the tissues with subsequent cicatricial formation, the presence of œdema for the first two days indicating the inflammatory nature of the reaction. The injection is carried out under anæsthesia, and for safety sake the buttocks are strapped together for 48 hours. Harmful results have not been noted, but in one case the injection had to be repeated 14 days later. Among the cases were some with prolapse the size of a child's fist, 8 cm. long, which immediately recurred after digital reposition. Prof. Eden thinks that the humanol, which is difficult to prepare, might safely be substituted by another more easily prepared neutral fat. L. Findlay and J. B. G. Galbraith[3] recently advocated in our own columns the use of absolute alcohol injections, and reported 41 cases so treated. 1·5 c.cm. are introduced in two places about ¼ in. outside the anal margin to a depth of 2–2½ in. All motions are subsequently passed in the recumbent position, and the buttocks are kept strapped together for a week. In the opinion of these writers the associated diarrhœa is more often the result than the cause of the prolapse. In 37 (90 per cent.) of the cases cure was complete, but in 3 of these the injection had to be repeated before this result was obtained, in 2 cases the condition was improved only, and in 2 no improvement took place. No cases of untoward effects were noted. The result here also was presumably obtained by cicatrisation occurring after inflammation, the sphincter recovering its tone during the period of strapping.

THE FEES OF MEDICAL WITNESSES.

IN a recent case in the Divorce Court Dr. A. M. R. Sinclair, who had been subpœnaed by both sides, when called into the witness box asked that his fees, as a witness, should be guaranteed before he gave evidence. He was perfectly correct in doing so, and we hope that no medical man who wishes to follow this example will be deterred by the tale which follows. Some discussion took place before the undertaking asked for was given, when it was settled that the side which actually called Dr. Sinclair should undertake to pay him a fee of 10 guineas, from which a guinea already paid as conduct-money would be deducted.

Mr. Justice Horridge took a considerable part in the discussion, and the tone adopted by a judge of the High Court towards a member of the medical profession giving evidence before him in a professional capacity requires notice. Mr. Justice Horridge said: "A great many people have to give evidence without making money out of it. They should have the satisfaction of knowing that they are taking part in the administration of justice." When Dr. Sinclair pointed out that he had been to the court on the preceding day and that it was a great waste of his time, Mr. Justice Horridge said: "I do not like to hear a professional gentleman of your position repeatedly telling me he is wasting his time. It is not a proper view to take." Later he said: "I do not care whether it is inconvenient or not. It is very often inconvenient for people to have to come to these courts but they have to come." After a registrar had been consulted as to the amount due, Mr. Justice Horridge further said: "He seems to me about as greedy a doctor as I have ever come across, which is saying a good deal, with regard to fees. But you must undertake to pay him 10 guineas. Then he must give his evidence or take the consequences."

His lordship's observations seem to us to misrepresent the position of a medical witness in civil proceedings. It is perfectly true that many witnesses assist justice by giving evidence without payment, and at a loss to themselves, and a medical man's duties as a citizen do not differ from those of any other layman when he gives evidence as such. When, however, he is subpœnaed in his professional capacity, in order that one of the parties in a civil suit may gain some advantage thereby, the position of the medical man differs from that of lay witnesses. He is then a professional man employed by one of the parties in the interest of that party on account of special qualifications which he possesses. He is not engaged, when called in to attend a patient [and paid for his time and knowledge, that later he may be called upon, outside the daily work of his profession, as a gratuitous witness. No contract is made or implied that at some future occasion he should employ hours, or days, assisting out of benevolence a plaintiff to secure a benefit or a defendant to avoid a loss. A medical man enters his profession with the object of making a living at it. He does not become a doctor in order to assist gratis in the administration of justice any more than does a barrister or a solicitor. As Mr. Justice Horridge has implied that in his personal experience greed is a characteristic of our profession, we may tell him that over and over again medical witnesses, rather than allow a poor patient unable to pay a suitable fee to suffer injustice for want of their evidence, have shown great generosity in such instances. No question of poverty, however, appears to have arisen in the case in question, and the party which called Dr. Sinclair was able to employ as an advocate one of the best known counsel at the bar. We sympathise with Dr. Sinclair in the position.

TECHNIQUE IN GRADING MILK.

IN connexion with the recent regulations as to graded milk, summarised in THE LANCET of last December,[1] the Ministry of Health have issued instructions as to the technical examination of the milk and cows. With regard to bacteriological examinations a circular, dated Jan. 13th, states that in the sampling of bottled milk, the whole bottle with the seal unbroken is to be taken, being carried and kept in ice until plated. Otherwise samples are to be taken in 4 or 6 oz. bottles, properly fastened and sealed, and similarly iced. Plating must not be delayed more than 12 hours; a special note must be made if plating takes place more than 30 hours after the time of milking or pasteurisation. The sample may be taken anywhere between the place of bottling and the consumer. Uniform methods of laboratory technique are to be employed by all official bacteriologists; the circular describes the exact method of making the plating medium, which will contain 3 g. of each peptone and Lemco and 15 g. of agar in 1000 c.cm. of tap-water, and will have a reaction to phenolphthalein of between 5 and 10 on Eyre's scale. Precise instructions are also given for making dilutions of 1/10, 1/100, and 1/1000 and plating in Petri dishes, which are to be incubated at 37° C. for 48 hours. Not more than half an hour is to elapse between the dilution of the milk and the pouring of the plates. If amongst the different dilutions there are plates containing from 30 to 300 colonies these are all to be counted, and the number, multiplied by the dilution, reported as the final count. Otherwise the plate that comes nearest to 300 is to be counted, and no plate with less than 20 colonies is to be counted unless there are none with more. If a plate contains more than 300 a part may be counted and the whole plate averaged. For "coli" tests tubes are to be prepared in the manner described, each containing 10 c.cm. of bile-salt lactose peptone water and a Durham's fermentation tube. This medium is made up with 5 g. each of sodium taurocholate and lactose and 20 g. of peptone in 1 litre of water, coloured with neutral litmus solution. One tube is to be inoculated with 1 c.cm. of the sample, two with 0·1 c.cm., and (in the case of Grade A) three with 0·01 c.cm. One uninoculated control tube is also to be incubated. The tubes are to be examined for acid and gas at the end of two days and three days. A special form is to be used for the report, signed by the inspector who took the sample, as well as by the bacteriologist, and stating the time of production, sampling, and arrival of sample at laboratory, the temperature on arrival, and the age (in hours) of the sample when examined.

In connexion with veterinary examinations Memorandum 77/Foods, dated January, 1923, indicates that for tuberculin tests fresh tuberculin of a satisfactory make is to be used, the manufacturer's name and the quantity used being stated in the report. The instructions supplied with the tuberculin must be adhered to. The animal's temperature is to be taken three times at three-hourly intervals shortly before injection, and the average noted. Any animal persistently showing an abnormal temperature should not be injected until soon after it has become normal. No animal is to be injected within three months of a previous tuberculin injection. The hypodermic and ophthalmic tests are to be applied simultaneously. After injection the temperature is to be taken every three hours from the sixth to the eighteenth hour, and the results of the eye test simultaneously recorded. If at the eighteenth hour the temperature shows distinct signs of rising, it should be taken again after three hours more. The temperatures must be taken by the veterinary surgeon or by an assistant working under his immediate personal supervision. The certificate is to be given in a prescribed form.

---

[3] THE LANCET, Jan. 13th, 1923.

[1] THE LANCET, 1922, ii., 1397.

In general veterinary examination, special care must be taken to exclude the following conditions: (1) Tuberculosis of the udder; (2) indurated udder; (3) enlargement of the supra-maxillary lymphatic glands; (4) tuberculosis in any form with emaciation; (5) chronic cough with definite clinical symptoms of tuberculosis; (6) anthrax; (7) foot-and-mouth disease; (8) mastitis; (9) abscess of the udder; and (10) retained placenta. The certificate must be on the prescribed form and must specify the clinical evidence; the milk-producer must remove from the herd any animal suffering from any of these diseases or any other disease likely to affect the milk injuriously, and give information showing how the animal has been disposed of, to the licensing authority.

THE INTERNATIONALISATION OF PUBLIC HEALTH WORK.

The Health Organisation of the League of Nations, with the assistance of financial support from the Rockefeller Foundation, has commenced the practice of interchange of public health personnel. A number of health officers are chosen by their own Governments to be sent to a specified country where they have the benefit of practical training. Lectures are given dealing with special health problems, and are illustrated by visits of inspection to private and public sanitary institutions. The first interchange of public health personnel took place at Brussels in October of last year, when 22 medical officers took part and eight countries were represented—Belgium, Bulgaria, Czecho-Slovakia, Italy, Poland, Russia, the Serb-Croat-Slovene State, and the Ukraine. The first half of the International Course came to an end at the beginning of November, and on Nov. 11th the medical officers taking part proceeded to Italy where they remained till Dec. 17th, when they returned to Geneva for a final conference. It having been decided that the next interchange of health officers should take place in England and Austria, Dr. D. C. Kirkhope, of the Society of Medical Officers of Health, was present at this conference.

All arrangements for the tour in Great Britain are being made, at the request of the Ministry of Health, by the Society of Medical Officers of Health. A special committee has been set up by the Society, with Mr. G. S. Elliston as secretary, and we are able to give the plan of the work, which, however, is subject to modification. The party, which will consist of 25 persons, will be drawn from 14 countries—viz., Austria, Belgium, Czecho-Slovakia, Denmark, Finland, France, Hungary, Italy, Norway, Poland, Roumania, Russia, Serbia, and Sweden. The officers will make their headquarters at the offices of the Society, 1, Upper Montague-street, Russell-square, W.C. 1. The first week will be spent in London, when they will study the central health administration at the Ministry of Health and the scheme of registration at Somerset House. They will also study the methods of the Metropolitan Water Board and the Metropolitan Asylums Board. Visits will be paid to the Museum of the Royal Army Medical College and to a typical example of the L.C.C. housing schemes. At the end of the week the party will break up into groups of four or five persons, so that they may study health administration. The areas chosen, with the principal officers responsible for conducting the course, are as follows: Birmingham and Warwickshire, Prof. John Robertson, M.O.H., Birmingham; Bradford and York, West Riding, Dr. J. J. Buchan; Glasgow and Lanarkshire, Dr. A. K. Chalmers; Liverpool and Lancashire, Prof. E. W. Hope; Manchester and Cheshire, Dr. Veitch Clark; and Newcastle and Durham County, Prof. Harold Kerr. The groups will remain in the areas to which they are assigned till March 28th or 29th. After the Easter holiday they will reassemble in London on April 3rd, and the three following days will be spent in studying port sanitary administration.

On April 11th the international representatives will depart for Austria with five British medical officers appointed by the Ministry of Health on the recommendation of the Society of Medical Officers of Health. Here a similar course will follow before the officers return to their respective countries.

THE STUDY OF ANIMAL DISEASES.

Since the period, some fifty years ago, when the development of the basic sciences reached a stage which appeared to promise a surer foundation for medical knowledge, our conceptions of the facilities required by research workers have undergone considerable change. The first stage was that in which, the waste of clinical material becoming obvious, research departments sprang up in close connexion with charitable institutions. It was soon found, however, that the scientific yield from human material alone had fairly rigid limitations. Investigations on human patients must be confined to observation uncontrolled by experiment, and progress under these conditions is slow. The recognition of this difficulty led to the second stage—the establishment of institutions, unconnected with hospitals, where the primary object should be research. Facilities for animal experimentation were provided, and the material consisted mainly of artificially produced lesions under experimental conditions. Valuable results have emanated from such institutions, but it is gradually becoming clear that the lack of accommodation for the study of naturally occurring disease is hampering progress. The modern demand is for hospitals of a different kind, hospitals where the primary object is the study of disease and where the welfare of the individual patient is subordinate to that of the many other sufferers, actual and potential, from the same disease. Obviously, no hospital for humans could ever fulfil this condition. The provision of stations for the isolation and experimental infection of animals with such diseases as tend to occur naturally among them is clearly the solution. Field laboratories already established in connexion with the University of Sheffield, with the Imperial Cancer Research Fund, and those about to be attached to the National Institute of Medical Research, may be expected to yield results of value not only to human but also to veterinary medicine. It was not until the further progress of human pathology was found to be handicapped by the lack of parallel efforts to grapple with animal diseases that it was generally realised how little time, money, and attention have been paid even to problems of enormous economic importance in this respect. The establishment of a chair of animal pathology at Cambridge, no less than the arrangements being made by the Medical Research Council for an exhaustive investigation into the pathology of distemper, is a sign that workers are at last preparing to cultivate a hitherto neglected field.

It is becoming obvious that in the interest of national economy alone problems connected with the ætiology, pathology, and therapeutics of diseases which afflict animals must be more actively attacked. The economic importance of concentrating on research into these diseases is well brought out in the last report of the Development Commission,[1] where the influence of the wastage caused by disease on the cost of production of, for example, meat and milk is shown. Practical farmers have been slow to recognise the position, but the reservation of a substantial sum out of the fund established by the Corn Production Acts (Repeal) Act, 1921, for veterinary research may be expected to encourage support from those most interested in the health of animals. There remains another cogent reason for the active study of veterinary pathology. Its advance by experimental methods will still further strengthen the case for animal experimentation, so persistently and tirelessly advocated by the Research Defence Society. In the current number of *The Fight Against Disease*[2] it is stated that this month the Society begins the fifteenth year of its work. During 14 years it has won many friends from among those who were ignorant of the need of animal experiments if medicine is to advance. It is now recognised that the distinctions between human and animal pathology and between human and veterinary medicine, are arbitrary, and that progress is interdependent. When it is realised that the results of such experiments are being used with a view to the alleviation of the sufferings of animals, as well as of humans, any opposition to the main means whereby a science of therapeutics can be built up must surely cease.

SUGAR, ALKALIES, AND ANÆSTHESIA.

The exact causation of vomiting after anæsthesia being still undiscovered, the use of remedies to prevent this after-effect must be at present empirical. Sugar in some form or another finds high favour with many surgeons and anæsthetists. There is at any rate this to be said in its favour, that it is rarely unacceptable to the patient, and in the case of children is swallowed with the greatest avidity to any required extent. Glucose is here given on the assumption that the vomiting is due to "acidosis," which in its turn is attributed to defective functioning of the liver. There is thought to be a call on the carbohydrates of the tissues. An increased store of glycogen in the liver cells, made possible by the intake of glucose, may assist the hepatic function and save the tissues. In patients with severe post-anæsthetic vomiting there is always diminished alkalinity of the blood; and, indeed, a slight amount of acidosis appears to be almost a constant concomitant of anæsthesia. There is evidence to show, however, that although glucose may reduce the percentage number of cases of vomiting, it does not materially reduce the number of cases of acidosis, making the two phenomena appear to be unrelated. Some authorities prefer to rely on free dosage with alkali during the day or two preceding anæsthesia for preserving undiminished the alkalinity of the blood, and they claim that this measure rather than glucose administration diminishes the frequency of vomiting. It seems an easy and safe compromise to give both bicarbonate of soda and glucose in small oft-repeated doses during the 48 hours preceding anæsthesia. We have heard of nothing but benefit from this practice.

At the Royal Society of Medicine on Feb. 12th, in the War Section, there will be a discussion at 5 P.M. on the Coöperation between the Members of the Medical Profession and the Medical Services of the Armed Forces, when short papers will be read by Surgeon-Captain A. Gaskell and Surgeon-Captain R. J. McKeown. The discussion will be opened by Air Commodore D. Munro and Major-General C. E. Pollock. Sir Crisp English and others will take part in the discussion. Sir John Goodwin, the President of the section, extends a welcome to visitors, whether members of the section or not.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

VI.

THE TREATMENT OF ABDOMINAL INJURIES.

Blows and Crushes.

The treatment of a patient who has sustained a crushing blow in the abdomen, such as might be produced by a cart-wheel passing over it, always causes grave anxiety. It is well known that in such an injury the patient may suffer severely from shock, and yet there may not be any gross injury of any of the contained viscera, nor any intraperitoneal hæmorrhage. This is an important fact to recognise, for otherwise the abdomen may be opened unnecessarily, and the shock thereby fatally increased. We must therefore have some evidence of serious intraperitoneal lesion, apart from the shock, before deciding on a laparotomy.

Indications for Operation.

What, then, would be the indication for operation as soon as improvement in the condition of shock allowed of this? Perhaps the most important general condition (and by this I mean the condition of the patient apart from physical signs) would be evidence of *increasing* shock. If the pulse was losing in strength, and getting steadily more rapid, or if the pallor were increasing, operation would be indicated. Even if the pulse gained in strength, and yet became steadily more rapid, I should regard that as a suspicious sign of grave abdominal injury. I have observed such a condition in a case of ruptured liver.

It is sometimes considered that the persistence of shock indicates that there is some grave lesion. But certainly it may be prolonged without. I have observed it persist in quite a marked degree for 18 hours after the injury, and yet the patient made a good recovery without any operative interference. The persistence of severe pain, especially if localised to any particular region of the abdomen, would be an indication for operation, and this must not be masked with morphine pending decision. The persistence of vomiting is regarded by some as an indication of damage to the viscera, but I have seen marked and persistent vomiting, associated with shock, after severe abdominal injury, followed by recovery without operation.

Physical Signs.

It is with reference to the presence or absence of certain physical signs that the surgeon has often to depend in deciding the question of operation. Of these one of the most important is shifting dullness in the flanks, as an indication of free fluid in the peritoneal cavity, which would almost certainly be blood. In the absence of very marked intestinal distension the presence of such shifting dullness would be a strong reason for immediate operation. But we must clearly recognise that after an abdominal injury there may be quite a large collection of blood within the abdomen, and no dullness, shifting or stationary. The blood may collect in the pelvis, and the distended intestines be floated up out of the pelvis; the abdomen may then present the signs of resonant distension, without any area of dullness, whereas all the time the pelvis may be steadily filling with blood.

The rapid development of a truly tympanitic abdomen would certainly be suggestive of the escape of gas from torn bowel, but not a gradually forming, moderate resonant distension. The absence of the liver dullness in a distended abdomen is of no value as a sign of free gas, and I have known it absent in an undistended abdomen, such absence leading to an unnecessary laparotomy. Even when the intestine is extensively torn there may not be any escape of gas into the peritoneal cavity. I operated on a case a few hours after an abdominal injury, and found the duodenum torn across, and no free gas present in the peritoneal cavity. Rigidity of the wall, especially localised rigidity, would be strong evidence of severe underlying injury. But though such rigidity would be a valuable sign if present, its absence is of no negative value. I have found it absent in ruptured intestine, and this has been the experience of other surgeons. The passage of blood from the bowel would seldom be an early enough sign to be of value in helping to decide the question as to the desirability of immediate operation. Vomiting of blood may be present after a blow on the upper abdomen, without any rupture of the stomach.

---

[1] H.M. Stationery Office. 1922. 3s. 6*d*.

[2] Macmillan. 6*d*.

I have so far been writing of the differential diagnosis of pure shock and injury of viscera or intraperitoneal hæmorrhage. In one of the gravest forms of abdominal injury—rupture of the intestine—no shock may be present, and the patient be able to walk to the hospital. In such a case a fixed pain, or rigidity of the abdominal wall, might indicate quite early the serious nature of the case. The absence of bruising of the abdominal wall does not negative a grave intra-abdominal lesion. The wall yields before the blow, or crush, and is not necessarily the seat of contusion. If the patient has not passed urine for some hours and has an urgent desire to micturate, but only a little blood-stained fluid escapes from the urethra, and the passage of a catheter shows that the bladder is empty, we have strong evidence that the bladder is ruptured, and this calls for immediate operation. In these cases there may be no shock, and if the patient is under the influence of alcohol, and no reliable history is obtainable, diagnosis may be very difficult.

Treatment of Shock.

In all cases in which shock is present it should be treated in the usual way by the application of warmth to the surface (by means of hot bottles) and by raising the foot of the bed considerably (not 6 inches or so). The result of raising the bed on small blocks is almost inappreciable on the patient's trunk as he lies in bed. The lower legs of the bed should be raised on chairs, and if the patient is a child lying on an adult's bed, he should be brought down towards the foot of the bed, so that he may get the full benefit of the tilted position. The most rapidly efficient remedy in combating profound shock is saline infusion by the intravenous method. If intravenous saline infusion is not resorted to, in view of the importance of keeping the bowels as much at rest as possible, and of a possible laceration of the colon, the subcutaneous method of introducing the saline rather than the rectal would be indicated.

Treatment Other than that of Shock.

The persistence of pain so severe as to call for a hypodermic injection of morphine would be suggestive of the need for exploration, and I have already called attention to the danger of masking the symptoms in this way. Moderate pain may be relieved by the application of a light fomentation over the abdomen. It is difficult to see how this can do any harm, and such drugs as aspirin may be safely administered. No nourishment should be given by the mouth whilst the question of laparotomy is being considered, so as to avoid any stimulation either of the stomach or intestinal activity. If great thirst is present, frequent administration of quite small quantities of water is a great relief to the patient, and can do no harm, but it is advisable to give directions to the nurse as to exactly how much each dose should consist of, or a really large drink might be taken.

Wounds of the Abdomen.

Exploration is desirable in all cases in which the depth of the wound is not obviously shallow. Probing is quite unreliable, for the track made by the weapon (perhaps a bullet track) may not be straight enough for the probe to detect penetration into the abdominal cavity, and such an opening, if it exists, may be plugged by a piece of protruding omentum. If penetration has occurred, from either a stab or gunshot wound, the intestine may be penetrated, without any shock, or other immediate indication of so serious an injury. If fæcal matter escapes from the damaged bowel it is not likely to be present in the wound, but to become diffused within the peritoneal cavity. If the patient has been stabbed, there *may* be fæcal matter on the weapon, but its absence would be no proof that the gut had not been injured. By comparing the entrance and exit wounds of a bullet, and mentally constructing its track, an idea may be formed as to whether it could possibly have damaged the intestine; but it must not be forgotten how far out the colon may extend, for if wounded even on its extraperitoneal aspect, it would require careful surgical treatment. If there was no wound of exit a skiagram would indicate the position of the projectile and thus the direction of the track. In all cases of doubt it would be safer to explore rather than to watch for symptoms. By exploration I mean exploration of the wound under an anæsthetic; this would probably necessitate enlarging it. If then penetration is found, the surgeon must be prepared to open the abdomen, and deal with any injury to an intraperitoneal structure he may find. This may involve the suture of divided bowel, but in some cases, particularly in gunshot wounds, he may have to perform an extensive resection of gut, with union of the divided ends, so that the exploration of the wound under an anæsthetic should only be undertaken by a surgeon sufficiently experienced to undertake resection and union of bowel. Once exploration has been decided on, it is an obvious advantage to keep the intestines as quiet as possible by the administration of a full dose of morphine hypodermically. The relief to the patient following this treatment must not be misinterpreted, and the surgeon must not allow himself to be persuaded by the patient or his friends that because he feels so much better no operation is necessary. Apparent improvement under morphine should never alter a decision to operate previously made.

CHARLES A. MORTON, F.R.C.S. Eng.,
Professor of Systematic Surgery, University of Bristol;
Consulting Surgeon to the Bristol General Hospital.

Special Articles.

THE FOLLOWING-UP OF CASES OF VENEREAL DISEASE.[1]

ONE of the most important questions in connexion with venereal disease is that of the following-up of the elusive patient who will not continue treatment until cure has been established. The seventh annual report of the National Council for Combating Venereal Diseases, covering the period from June, 1921, to the end of June, 1922, contains an analysis of replies received by the Council to a questionnaire which was issued to members of the Council, and to branches and organisations represented on the Council, as one means of collecting evidence of opinion with a view to the introduction of legislation. 75 per cent. of replies favoured the giving of powers to health authorities to compel persons suffering from infective disease to remain under treatment; 79 per cent. were in favour of fresh legislation. 32 per cent. of replies expressed the belief that public opinion in their districts was ripe for a demand for legislation; 20 per cent. expressed the opposite view, the remainder being doubtful. Various alternative methods of protection for the public were suggested by the dissentients, the proposals covering (1) the reporting by medical officers of venereal disease clinics, and by private practitioners, of cases of syphilis and gonorrhœa in infants, children, and adolescents up to the age of 18 to the school medical officer with a request that the school nurse might follow up cases which failed to attend; and (2) Government action making it compulsory for every medical man to treat his own patients. 91 per cent. of replies attached importance to the proposal that legislation concerning the suppression of venereal disease should be a public health matter, and should not be combined with legislation aiming at the suppression of prostitution; 92 per cent. favoured the confidential treatment of persons willing to continue such treatment until they are non-infective, and notification of those who discontinue treatment while still infective; some replies favoured the first part of this proposal, but not the second. 85 per cent. of those persons or bodies questioned saw no reason why public health regulations requiring the compulsory continuous treatment of infective persons should not be impartially administered between the sexes. There was apparently general agreement that any limited form of notification and compulsory treatment introduced should only be operative towards those who had discontinued treatment, and that otherwise confidential treatment should be retained.

---

[1] Seventh Annual Report of the National Council for Combating Venereal Diseases, June, 1921–July, 1922. Published by the Council, 80, Avenue Chambers, Southampton-row, London, W.C. 1.

In our last issue we dealt with the report of the Committee appointed by the New Zealand Minister of Health to inquire into the position with regard to venereal disease in the Dominion. Among the recommendations of the Committee was one relating to legislation providing for "conditional notification of venereal disease," by which it would be the duty of a doctor to notify to the Health Department, by number or symbol only, each case of venereal disease he treated. The terms of the recommendation were that if a patient refused to continue treatment until cured, and would not consult some other doctor or attend a clinic, it should then be the duty of the doctor to notify the case by name. If the patient continued recalcitrant, the Director-General of Health should be empowered to apply to a magistrate for the patient's arrest and detention in a public hospital or other place of treatment until he should be non-infective. The Committee also recommended provision to deal with cases where persons suffering from venereal diseases were not under medical treatment and were likely to infect others. The Director-General should be empowered to call on such a person to produce a medical certificate, which might be procured free of charge at any hospital or venereal disease clinic. If the person refused to produce such a certificate he or she could then be taken before a magistrate, who might order a medical examination. Penalties, including detention in a prison hospital, should be provided for recalcitrant cases, and all proceedings should be private unless the defendant desired a public hearing. Action along these lines has already taken place in Queensland, as recorded in the annual report for 1922 of the Commissioner of Public Health for the State. "In accordance with Section 159 (6) of the Health Acts, 1900–1917," 448 male patients attending the Brisbane clinics were notified for failing to report themselves at least once in every four weeks. Of these, 418 were written to and warned of the consequences of their action; 205 thereupon reported back to the clinic or official advice was received that they were again under medical treatment for venereal disease. The services of the police were requisitioned in 221 cases; the result of their action in these cases, and in 127 cases regarding whom no information was at hand on June 30th, was as follows: Not traced, 208; warned, 74; dead or left State, 13; in gaol, 2; certificates of cure received, 6; reports not to hand regarding 45. Nine of the patients who did not comply with the warnings given them were proceeded against, and fines ranging from £2 to £5 were imposed. Three other defaulters were found to have left the State, and proceedings against them were withdrawn. Four of the women attending the female clinic were written to during the year for failing to continue medical treatment, with the result that three again reported, and the other transferred to another medical practitioner, from whom the requisite official advice was received. Another woman, written to in the previous year, was warned by the police, and on reporting was found to be free of the disease and given a certificate of cure.

The Council for Combating Venereal Diseases, having considered the American system of notification by number and compulsory detention, and various Continental systems, state in their report that these contain possibilities of grave abuse, their administration tending to result in a form of regulated prostitution, the compulsory clauses being exercised largely in relation to women. Dominion legislation, like that quoted above, being more in accordance with principles acceptable in this country having been applied in the Dominions, the Council communicated with the Provincial Health Departments in Canada; the replies received showed that Canadian medical officers are practically unanimous in believing that the system of confidential notification does not prevent people seeking treatment. The N.C.C.V.D. finds in this country evidences of a steadily-growing public opinion in favour of some form of compulsory continuous treatment.

HONOUR TO THE STRETCHER-BEARER.

"DANS LES BOUES DE LA SOMME."

The Service de Santé, the medical corps of the French Army, was recently honoured by the city of Paris, which presented to the Medico-Military School of Val-de-Grâce a fine sculptured group representing two stretcher-bearers carrying a wounded man to safety through the mud of the Somme. This group, exhibited at the Salon in 1921, and bought by the Fine Art Commission of the city, is the work of a young sculptor, Mr. Broquet, who was himself an infantry stretcher-bearer and was wounded during the war. The group has been set up in front of the main entrance, at Val-de-Grâce, as a monument to the valour of the "other ranks" of the Service de Santé, the officers being commemorated by their names on memorial tablets dedicated on the same day, during May, 1922. The President of the French Republic, the Minister of War, the President of the Municipal Council of the city of Paris, Marshal Joffre, and other notable persons were present; the occasion

A sculptured group representing two stretcher-bearers carrying a wounded man to safety. The group in its setting in front of the main entrance of the Val-de-Grâce Medico-Military School, Paris.

A nearer view of the group, giving more detail.

took the form of a national tribute to the medical service of the army. Mr. César Caire, the president of the Paris Municipal Council, recalled that wherever the "poilu," the real victor of the war, had gone forward, the stretcher-bearer had always been with him to succour him if he fell. Mr. Viry, a senior medical officer, and president of the Friendly Society of Past and Present Students of Val-de-Grâce, regretted it had not been found possible to commemorate on the memorial tablets the names of the auxiliary medical officers who had fallen in the war; only those of the regular service appeared, space and money being alike wanting. Others who should also be commemorated were the 69 chaplains, and many nurses who were killed. One hundred and ten doctors had been killed; 9000 stretcher-bearers had died, 5000 of them from wounds in action. The tablets and the monument were accepted on behalf of the school by the Director, Medical Inspector Jacob, who pointed out the realism of the group, which he said, portrayed the kind of thing many of those present had seen on the battle-fields of the Somme. The work of the stretcher-bearers, he concluded, had saved 60 per cent. of the French wounded, which meant that from February, 1918, to the Armistice they returned half a million of men to the firing line. Mr. Maginot, Minister of War, associated himself with the homage there rendered to the Service de Santé, officers, stretcher-bearers, and nurses, whether of the regular service or of the reserve. At the conclusion of the proceedings, Mr. Millerand, President of the Republic, presented to the school the Croix de Guerre, granted because of the devoted pursuit of science and spirit of sacrifice for others displayed therein during the war.

We are indebted for the photographs here reproduced to Dr. Visbecq, Médecin Chef de la Section Technique, Service de Santé, Paris.

Public Health Services.

Some Points from the Guildhall Conference on Health Insurance.

The procedure at the Guildhall Conference of bodies interested in the medical service under the National Health Insurance Acts necessarily resulted in the ventilation rather than the orderly discussion of difficulties. For their solution we must await the formation of sectional conferences by the Standing Committee appointed at the Conference. Nevertheless, some important points were made. Sir William Glyn Jones, in his opening remarks on "Title to Benefit," brought out the fact, which is hardly yet generally recognised, that panel doctors are not paid for individual insured persons on their list but that they collectively are responsible for the provision of medical benefit to the whole of the insured persons in the area. The share of the local pool due to each individual practitioner is measured by the relation of his list to those of his colleagues. The figure is measured in units of credit, the credit varying with the acquisition of newly signed medical cards and the loss of record cards, which the practitioner has to return to the insurance committee to be transferred when the insured person elects to make a change of doctor. Migration of population and change of address among insured persons have rendered registration both difficult and costly. But its total abolition on the score of economy would lead either to payment on an attendance basis or to a State service. Sir William Glyn Jones was probably right in suggesting that more accuracy would prove too expensive and that it was doubtful whether doctors would do better on any other system.

In the discussion on "Efficiency of Service Rendered" surgery accommodation was the first and indeed the main subject of criticism. Mention was made of the "insanitary atmosphere in the waiting-room," and speakers on the medical side admitted defect. It must be remembered, however, that in industrial areas the housing shortage has made it very difficult for medical men to find suitable premises, and that the cost of adapting old houses has been prohibitive. The matter rests in the hands of the insurance committees, and panel committees have shown little reluctance to assist in securing all-round improvement. The insured person has his own preferences which are not necessarily hygienic. We call to mind a suburban area where insured persons crowd on to a practitioner's list because they like the open surgery system, although the accommodation is not to be compared with that of a professional neighbour who admits them by the front door into his single consulting-room and a well-furnished surgery where he sees private patients as well. The desire expressed by trade-union representatives that the doctor should furnish insured persons with private cards showing surgery hours and the names of his partners is already met in many places.

The Medical Service Subcommittees came in for much adverse criticism. These tribunals are admittedly not as effective as they might be, but it is difficult to see what could be put in their place. They actually serve a useful purpose, and so long as the system remains of admitting all registered practitioners to the panel there must be some instrument for reviewing the service and winnowing out the chaff. Sir Alfred Warren, one of the whilom severest critics of the medical service, spoke up for these much-abused committees, hinting that approved society representatives were only treated as hostile witnesses when they acted as such. No doubt there is room for education in all parts of a health service, for here efficient work implies that each unit must know how best to coöperate with every other.

Public Health in Local Acts.

Parliament passed 120 local and private Acts during 1922. Their provisions for local gas, water, and electricity undertakings, for trams, railways, and canals, for drainage, pilotage, and fisheries, and for schools, trusts, and Irish divorces are neither very exhilarating to read nor very easy to find, but there are some instructive passages about public health which are worth exploring. For if we find out what new powers our local authorities are obtaining, we can see in what respects the general standards laid down for the whole country by the Public Health Acts are thought to be inadequate. Public health legislation in England has usually thus developed from the particular to the general. One progressive municipality takes a step forward; others move up abreast of it; and finally the pace they set is taken up all over the country and the whole line moves forward together. It was a local Act obtained by Manchester in 1844 which formed the basis of much of our first Public Health Act in 1848. The same tentative and experimental method is still at work to-day. Here, then, in the local Acts of 1922 we can see the latest developments for which keen medical officers and enlightened bodies of borough councillors are pressing. They may not be the first examples of their kind, but they are good evidence of progress.

The boroughs of Cambridge and Ramsgate and the urban district of Padiham have improved upon the national standard by prohibiting the insanitary practice of blowing out carcasses of meat. Butchers who inflate their meat may find it costs them the not very severe penalty of £5. The councils of these same areas and of Doncaster are empowered to make by-laws requiring that meat or other articles of food must be covered while conveyed along any street, road, or place, and that all carts and receptacles for such food be properly clean. Other useful local provisions are those which direct that all dwelling-houses to be erected in future must have "sufficient and properly-ventilated food storage accommodation." At Neath and at Worthing no room or shop where human food is sold, prepared, or stored is to be used as a sleeping place. Doncaster and Ramsgate are insisting that the manufacture of potted meat be carried on only in premises registered for the purpose by the occupier, with a saving clause for hotels. Regulation of the manufacture of ice-cream is not uncommon, and sections which forbid rag and bone dealers to sell food also appear. The Cambridge Act prohibits the use of inedible fats in food.

Many local authorities, including the London County Council, had their hands strengthened by Parliament in 1922 for dealing with verminous persons and filthy premises, and for disinfection against tuberculosis. The infectious and contagious diseases provisions of more than one local Act prohibit infected persons from knowingly engaging in any occupation, trade, or business connected with human food in any manner likely to spread disease. The names of laundrymen to whom clothes from infected houses are sent must be furnished to the medical officer; there is also power for the latter to make medical examinations of the inmates of common lodging-houses where infection is suspected. Compensation may be paid to persons who, at the request of the council or the medical officer, stop their employment for the purpose of preventing the spread of infection. In all the districts already named there is to be a firmer control of Sunday schools and places of entertainment as the potential disseminators of diseases amongst children. Power is taken to close Sunday schools and to make parents keep their children at home. While nothing more was heard of the Smoke Abatement Bill, which the Minister of Health proposed to introduce last summer, and to which the report of Lord Newton's Committee and the conference at Oldham drew attention, Cambridge has meanwhile taken action against the smoke nuisance. There will be a fine for the owner or occupier where, in factories, baths, and washhouses, or places where engines are worked by steam, fireplaces or furnaces are not so constructed as to consume their smoke.

Of course, it does not follow that because a local authority obtains the power to make a by-law, the by-law will necessarily be made or, if made, enforced by adequate penalties. Local authorities live under the shadow of the doctrine of ultra vires. They like to take powers even if they do not immediately use them. Hence the details in these local Acts. If Ramsgate wants to set up an information bureau or to regulate mixed bathing, or if Weymouth wants to run a municipal golf course, it must come to Parliament. But the possession of these by-law-making powers is immensely educative and stimulating. If we find that Bolton or Neath or Worthing have got authority to inspect taximeters, we begin to wonder what is done elsewhere in the country to protect the casual passenger from the not always scrupulous taxicab man. So with public health. The local Acts show the maximum progress of the few. If their advanced standard is reasonable and right, the rest of the country may ask why these provisions are only to be found in local Acts.

Correspondence.

"Audi alteram partem."

THE BRITISH RED CROSS IN GREECE.

To the Editor of THE LANCET.

SIR,—The Chief Commissioner of the British Red Cross Society in the Near East, telegraphing from Athens, concerning the desperate conditions existing amongst the refugees in Greece, including thousands of British subjects from Asia Minor and Thrace, urgently recommends that the Society immediately take over the medical side of the local British Committees' work in Athens. They are badly in need of medical supplies and personnel with which to prevent the spread of various devastating epidemics and to alleviate the distress amongst that portion of the refugee population entrusted to their charge.

The Greek Government are quite unable to cope with the pressing demands made upon them, and the British Committee are doing their utmost, with inadequate means, to assist them. The Society appeals to the British public to support them at once. From Lady Rumbold's Hospital, already established at Dedeagatch in Western Thrace, with 300 beds, assistance could be sent to the villages in the surrounding country. At least three clearing hospitals of 100 beds each are urgently needed in Western Thrace.

The Society therefore earnestly appeals for funds to carry out the work, which will be entirely under the supervision of their officers in the Near East. Epidemic diseases are spreading with great rapidity amongst the refugees who, as stated, include large numbers of British subjects and others of the Christian faith.

Subscriptions should be sent to the Honorary Treasurer of the British Red Cross Society, 19, Berkeley-street, Mayfair, W. Gifts in kind and clothing, which are badly needed, should be sent to the warehouses, 71, Southwark Bridge-road, S.E.

I am, Sir, yours faithfully,

A. STANLEY.

Feb. 5th, 1923. Chairman, British Red Cross Society.

GASTRIC ULCER AND GASTRIC CANCER.

To the Editor of THE LANCET.

SIR,—The acknowledgment by Sir Berkeley Moynihan in his Hunterian Society address [1] of the radiological diagnosis of gastric ulcer as the only definite and certain one is gratifying to those of us who have laboured in this field. My own first series of typical radiograms of chronic gastric ulcer appeared in the Proceedings of the Royal Society of Medicine in 1913. The slides shown by Sir Berkeley Moynihan closely resembled mine of ten years ago. They showed (1) the "niche"—i.e., the base of the ulcer filled with bismuth. (2) The "notch" in the greater curvature, or spasmodic hour-glass constriction of the stomach at the level of the ulcer. Sir Berkeley Moynihan's slides (like mine) showed other features constantly present in gastric ulcer. These include (3) the pronounced dropping and enlargement of the pyloric portion of the stomach—the portion beyond the ulcer. (4) The tense pylorus. (5) The dilated and distended duodenum. These are the chief features to be made out from the photographic plate, but other evidence of the greatest importance and constancy is to be derived from observation with the fluorescent screen. The pyloric distension is seen to be due to strong gastric peristaltic waves beating up against a pylorus which is held closed by spasm—spasm so tight that it imprisons bismuth in the pyloric portion of the stomach for 50 or 70 hours. The distended duodenum is shown to be in a state of most active peristalsis; it is making powerful efforts to overcome a stubborn kink at the duodeno-jejunal junction. In its efforts the duodenum writhes like a serpent. The radiological examination of the stomach and duodenum does not, however, complete the information which the X rays can afford. The bismuth should be followed through, and the investigation finished with a barium enema. In the ileo-cæcal region will be found one or other of the abnormal conditions referred to by Sir Berkeley Moynihan in his lecture: An adherent appendix, anchoring the cæcum and impeding the flow through the lower ileum; an ileal link; a dropped and rotated cæcum causing ileal torsion. In the large intestine will be found, in every case of chronic gastric ulcer, ample evidence of old stasis.

---

[1] THE LANCET, Feb. 3rd, 1923, p. 231.

A gastric ulcer is no capricious happening; it is no chance mishap to a healthy member that has given no provocation. A gastric ulcer marks the breakdown of an organ which has been living an unhealthy life in a vitiated environment. When will the eyes of the medical world be opened to this evident truth? Sir Berkeley Moynihan referred to the controversy as to the origin of gastric cancer in chronic ulcer. In my view he is right in insisting that ulcers frequently become cancerous. I am aware that some have asserted that a carcinomatous nodule may appear in the stomach, and that the stomach may attempt to rid itself of the growth by creating an ulcer at the site of the nodule. If this ever occurs it is a pathological curiosity. Radiology gives the strongest possible support to Sir Berkeley Moynihan's view. The form of a chronic ulcer of the lesser curvature, as shown radiographically, is remarkably constant—almost as constant, say, as the form of a fiddle. Now and then the radiologist shows a chronic ulcer, perfectly typical except for one or more slight irregularities of the usual ulcer outline. These irregularities are found, at operation, or on section after excision, to be carcinomatous.

So far Sir Berkeley Moynihan took us with unerring step, but radiology takes us a great deal farther. I have referred already to the exact radiographic resemblance of a gastric cancer, in its early stages, to a chronic ulcer. The resemblance is no mere superficial one; it is fundamental. Not only have we the "niche" and the "notch," we have the big, dropped pyloric portion; the tight pyloric spasm; the distended, "writhing" duodenum. Nor is this all. If we follow the bismuth through (as we should in all cases), we find one or other of the same changes in the ileo-cæcal region, and we find again the evidences of old stasis in the large intestine. No one has a right to assert that cancer of the stomach is a chance happening. It is the final breakdown of a diseased organism; one still capable of carrying on life's functions without obvious failure, but still a diseased organism that has lost its capacity to resist malign influences.

I am, Sir, yours faithfully,

ALFRED C. JORDAN.

Upper Wimpole-street, W., Feb. 3rd, 1923.

THE TREATMENT OF GASTRIC AND DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—Sir Berkeley Moynihan's Hunterian Lecture on Gastric and Duodenal Ulcer, the report of which is published in your last issue (p. 231), reopens the question of medical and surgical treatment in these conditions. It cannot be denied that in many cases where such ulceration has produced extensive fibrosis, adhesions, and organic obstruction, surgical measures directed towards the stomach are inevitable. When, however, the diagnosis of ulcer has been made in the earlier stages, before such changes have occurred, it is open to question whether medical or surgical treatment should be advised.

Any method of treatment must have two objects—the healing of the ulcer and the prevention of its recurrence. An enormous amount of research has been carried out to determine the factors which produce peptic ulceration and which interfere with its healing; many predisposing and exciting causes have been suggested. One fact, however, would appear to be predominant—namely, the action of acid pepsin of the gastric juice on an area of devitalised mucosa, such devitalisation being the result of toxins introduced by the mouth or carried by the blood-stream from some distant focus of chronic infection. Healing is interfered with by the persistence of these factors, probably assisted by gastric distension, constipation, loss of blood, and malnutrition due to prolonged restriction of the diet. Medicine attempts to deal with these conditions by means of dietetic and alkaline treatment. The diet is so arranged as to be easily digested and palatable, but at the same time plentiful, meals being frequent and of moderate size in order to avoid gastric distension. The diet used is fat and protein rich and carbohydrate poor. The fat is used for its calorific value and its influence on secretion, the carbohydrate is restricted largely because the chief form in which it is taken—vegetables—provides bulk rather than energy, and bulk means gastric distension and mechanical irritation, which it is desirable to avoid. Combined with this dietetic regulation is the administration of alkalies. The object of such alkaline treatment is not so much to combat any hyperactivity of acid secretion, which may, or may not, be associated with peptic ulcer, as to produce and maintain complete neutrality of the gastro-duodenal contents. In so much as pepsin can only act in an acid medium, neutralisation of that medium renders it inert and consequently removes one of the most important factors, causing and maintaining ulceration both in the stomach and duodenum. To achieve this suitable drugs must be administered in suitable quantities. The treatment must, it is true, be continued for a considerable time, but, as the diet consists of ordinary foodstuffs prepared in ordinary ways, it is neither impracticable nor irksome for the majority of people.

But there still remains the most important factor—the cause. If it be not removed, treatment cannot be successful. The cause must be carefully searched for, and, if necessary, surgical measures must be undertaken directed towards the eradication of chronic infection. Surgical treatment of the ulcer is by means of gastro-enterostomy, cauterisation, gastrectomy, &c. This is undoubtedly a radical treatment of the effect, but the cause which has produced the ulcer remains.

That medical treatment in the past has not been too successful is mainly attributable to: (*a*) unsuitable and unpalatable diets; (*b*) failure to fulfil completely the aim of the alkaline treatment; (*c*) concentration on the treatment of the effect—the ulcer—rather than on the cause. If ulcer be diagnosed in its early stages, it should not be impossible to cure it by medical treatment combined with minor surgical measures, directed not towards the stomach, but towards the cause, which lies outside the stomach. Unfortunately the diagnosis of peptic ulcer is extremely difficult by clinical means. The main symptoms are not characteristic of ulcer, but are merely the expression of disturbed gastric function—dyspepsia—which may be equally produced by reflex, nervous, and other factors. Ulceration itself has little in the way of definite or clear-cut clinical symptoms, even hæmatemesis being usually due to diseases of the liver and spleen.

Careful evaluation of the symptoms of dyspeptics, thorough investigation of their causes, combined with adequate and rational treatment, will go a long way towards the prevention of ulcer. When ulceration has occurred, its early diagnosis, which is almost impossible without X ray assistance, should make medical treatment both useful and practicable, and minimise the need for serious and extensive operative measures.

I am, Sir, yours faithfully,

Manchester, Feb. 5th, 1923. NORMAN KLETZ.

EDUCATION IN CANCER PROBLEMS.

To the Editor of The Lancet.

Sir.—I am afraid I cannot quite agree with your editorial in The Lancet for Sept. 23rd, 1922, or, at least, with the statement that a campaign of education cannot diminish the incidence of cancer. I find it difficult to believe that if the natives of the Philippine Islands were to stop chewing betel nut, the occurrence of cancer of the cheek among them would not be considerably reduced; or that if the natives of Kashmir were to cease using the kangri basket, cancer of the anterior abdominal wall would not become the rarity that it is elsewhere. Among more civilised peoples there are other sources of chronic irritation, not always so obvious, certainly, yet often susceptible of control or eradication. If these could be abolished, would not the incidence of cancer be lessened? As an example of the sort of lesion that I have in mind, it will suffice to say that we almost never see cancer of the mouth in the United States among the class that is sufficiently high in the social scale to keep this cavity in a clean and healthy condition.

But suppose that a cancer has once started somewhere in the body. Need the situation, even then, be so hopeless as that editorial would have us believe? In the United States, an average period of one year elapses between operation and the first appearance of cancer. Can this period not be shortened; and if it can, may we not expect more than prolongation of life for a few years, as the editorial suggests? We in the States think that the length of time between discovery and operation can be shortened. For we believe that a public which has been taught that tuberculosis is often curable in its early stages, and that the cure for appendicitis is more often surgical than not, can also be taught the relation between chronic irritation and cancer, the earliest signs and symptoms of this disease (in so far as these are known), and its curability if removed in time.

Nor is the belief unjustified. Several American cities now have data to show that the number of early cases of cancer applying for advice has steadily increased since the inauguration of a campaign of education only a few years ago. So we think it the right of every woman in the cancer age to know that slight bleeding, continued throughout the month, may have nothing to do with the menopause but may mean an early, and therefore an operable, cancer of the uterus; and that a small painless lump in the breast may be a cancer which can be removed with good promise of success if there be no delay. And we wish every man over 40 to realise that hæmaturia, or a small painless ulcer about the mouth, or dyspepsia that does not yield promptly to treatment, may be the first warning of death within a year or two, unless prompt action be taken.

The fact that cancer of an internal organ often remains undiscovered until too far advanced for operation is not, in my judgment, a reason against educating the public in respect to the more easily diagnosed cancer of the mouth, breast, and uterus—types now responsible for a number of deaths too large by far.—I am, Sir, yours faithfully,

Wm. H. Woglom, M.D.,
Associate Professor of Cancer Research.

Institute of Cancer Research, Columbia University,
in the City of New York, Jan. 22nd, 1923.

*** We do not object to a public campaign of education; our objection is to the public being led to believe that by spending money on an educational campaign of any kind they will enable the medical profession to prevent or to control cancer. In the present state of our knowledge such a campaign cannot possibly diminish the incidence of the disease. We cannot tell the public which particular form of chronic irritation is responsible for cancer of the breast, of the uterus, of the stomach or rectum, to mention only some common sites. We cannot, therefore, instruct them how to avoid these chronic irritations. To warn the public against all forms of chronic irritations would be to open the door wide to all faddists. According to the work of some American investigators heredity is a factor at least as important as chronic irritation. Are we prepared, then, to go before the public and throw a shadow over the life of every person whose parents or grandparents have died of cancer? Are we prepared even to advise against the marriage of two persons who have a family history of cancer? What we advocate in short is that we should be honest with the public. We should encourage them to seek medical advice and submit themselves to operation at the earliest opportunity. But we must make it clear to them that this is palliative treatment with an uncertain promise of cure. We should not call it the prevention or control of cancer.—Ed. L.

THE INTER-RELATIONS OF TUBERCULOSIS AND RICKETS.

To the Editor of The Lancet.

Sir,—In your issue of to-day's date there is a report of the meeting of the Society of Medical Officers of Health held on Jan. 19th. I was glad to see that Dr. W. J. Howarth has added the effect of sunlight to the evidence I put forward in *Tubercle* of last December, of the parallelism and possible relationship between rickets and tuberculosis as deficiency diseases. This is an interesting and important addition.

I do not think that tuberculosis can be regarded purely as a deficiency disease. So far as we know now, the addition of the necessary factor to the diet will completely cure any deficiency disease at whatever stage the patient may be, although certain results—e.g., mis-shaped bones—may be left. This, unfortunately, is not the case with tuberculosis, either pulmonary or surgical, as we know it. It may be that infection by secondary organisms terminates the period of tuberculosis as a purely deficiency disease, but this is, at least, very doubtful. Nevertheless, there is considerable evidence that rickets has a causal relationship to tuberculosis.

I am, Sir, yours faithfully,
V. F. Soothill, M.D., D.P.H.

Council Offices, Ilford, Essex, Feb. 3rd, 1923.

"CENSURE AT AN INQUEST."

To the Editor of The Lancet.

Sir,—The above heading, which is becoming unnecessarily frequent, is taken from the *Sunday Times* of Feb. 4th. The facts appear to be that a woman died suddenly within half an hour of her reception into hospital, and the house surgeon, who had the advantage of a history of the case, obtained permission from the friends to make a post-mortem examination. As a result of the sectio he became suspicious of poisoning and took certain steps, not free from criticism, to obtain a chemical analysis. The coroner, a doctor, is reported to have said: "He (the house surgeon) had no right either to give a certificate or undertake a post-mortem examination. . . . It was Dr. S.'s duty to have reported the case to him at once. . . . What he had done had been both irregular and wrong. A sudden death, and one the cause of which was unknown, should always be reported to the coroner at once." However much in error the house surgeon may have been in not labelling his bottles and in failing to notify the coroner when he discovered a prima facie case for special investigation as to poisoning, the coroner himself is in at least equal condemnation in his misreading of the law if he used the words reported. A medical man can (*a*) always give a certificate and leave the responsibility for accepting it to the registrar (see the Registrar-General's statement [1]); (*b*) perform a "sectio" having obtained consent from the relatives or other responsible person. It is no part, as admitted in the authoritative statement of the Registrar-General already referred to, of a medical man's duty to inform the coroner whether the death be sudden or no, notwithstanding that occasion may arise when it would be both prudent and convenient to do so.

---

[1] The Lancet, 1887, i., 1144.

One might anticipate from a member of the medical profession, holding a public position of dignity, a little consideration for a young colleague who has departed from the strict line of prudence albeit not of law. His censure on this young practitioner, and through him on the profession as a whole, has become the subject of much erroneous public comment.

I am, Sir, yours faithfully,
H. A. BURRIDGE.
King's College Hospital, S.E. 5, Feb. 6th, 1923.

THE DIAGNOSIS OF SMALL-POX.

To the Editor of THE LANCET.

SIR,—The difficulty which is sometimes experienced in making the diagnosis of small-pox is a subject not infrequently referred to in the medical press. The diagnostic value of vaccination in some such cases does not appear to me to be sufficiently recognised. Vaccination has not very infrequently "taken" in patients the subject of small-pox up to the end of the first 48 hours period of the *rash*, but, I believe, never later. Therefore, if vaccination "takes" later than this, the very strong presumption is against the disease being small-pox.

In West Africa small-pox has not infrequently been diagnosed from the appearance of the rash, and active measures based on the diagnosis, but vaccination has been effective in the patients subsequent to the period mentioned above as the extreme limit for successful vaccination in cases of small-pox, and the diagnosis was thus in my opinion proved incorrect. The most helpful point to me in differential diagnosis in West Africa, so far as the rash was concerned, was the development of the rash within a skin area of a few square inches. If papule and vesicle or vesicule and pustule are found at the same time in relatively close proximity the disease is almost certainly not small-pox either in a European or native West African.

I am, Sir, yours, faithfully,
Liverpool, Jan. 26th, 1923. R. H. KENNAN.

THE DIPLOMA IN PUBLIC HEALTH.

To the Editor of THE LANCET.

SIR,—The leading article in your issue of Feb. 3rd sets forth clearly and fairly considerations in favour of modifying the new rules for Diplomas in Public Health which are to come into force next year. I shall be glad, however, if you will allow me to state some points on the other side.

The two years' interval between qualification in medicine, surgery, and midwifery, and that in public health is intended to provide for a somewhat greater maturity of thought and outlook on life than the newly fledged licensee or graduate can possess. Specification of how the time may be spent which is not occupied in preparing for the D.P.H. examinations is deliberately omitted. It may be spent in a hospital or laboratory, or as assistant in general practice or otherwise, but whatever be the line followed, a man should be all the better qualified after two years or more have elapsed to enter on an official career which will bring him into daily and responsible contact with the public, public authorities, and his professional brethren in general practice.

The purpose of the six months' practical training under a medical officer of health is obvious; so also is the requirement that he shall, in addition to the wide subject of environmental hygiene, have had administrative instruction in the newer activities of local health authorities—maternity and child welfare, school medical inspection and treatment, &c.—all as set forth in the rules. These are based on the belief that such training is necessary for the health officer. Assuming that to be granted, the time must be found, and in the case of men in Army or Navy or Colonial service, it is a question of study leave. No doubt there may or will be difficulties, but such difficulties are involved in every extension of every professional curriculum, and have to be faced by those concerned. It can hardly be contended that the sanitary staff officer of an army corps has commonly at his disposal facilities for much of the training and instruction now to be required. The same observation applies to the four years "tour of service" in tropical or sub-tropical regions, and to work in India. Can such service give the training to suit a man for an appointment in this country, for which the Diploma in Public Health is primarily designed? I think there must be a misunderstanding as to non-acceptance of training by sanitary officers in the colonies. The rules do not limit the term medical officer of health to men occupied in this country. If the medical officer of Sydney or Melbourne or Montreal or Toronto or Cape Town can give the necessary certificate of instruction in practical hygiene and in all the items (*a*) to (*f*) required by the rules, surely the candidate's training would not be rejected either by a licensing body or by the Medical Council; but inquiry can elicit a reply on that point. The whole curriculum, it should be explained, can be compressed within 10 months, so extending over 12 calendar months.

Briefly, it may be freely admitted that the new diploma will be more difficult to obtain than the old, but when obtained it will mean more. The standard does need to be raised in the interests of the public; all students of medicine are in future to receive regular and specific instruction in preventive medicine, and at the same time men aspiring to official appointments in the local health service will require a higher training than has been necessary heretofore, and the country will reap the benefit. I should, perhaps, explain that being no longer a member of the General Medical Council, I have felt free to state my views directly on the important subject you have raised.

I am, Sir, yours faithfully,
London, Feb. 6th, 1923. JOHN C. MCVAIL.

THE R.M.B.F. GUILD.

To the Editor of THE LANCET.

SIR,—You have been so kind in giving publicity to the work of the Royal Medical Benevolent Fund Guild that we are venturing to draw attention to a point which did not receive sufficient prominence at our festival dinner—namely, that the Guild is fortunate enough to have interested the Drapers' Company in its work, and they have awarded two grants from the Pennoyer Fund to two of our beneficiaries—a boy and a girl—and they have also nominated another girl to a vacancy in Elmslea School. Similarly, the governors of Guy's Hospital have awarded a nomination to Christ's Hospital to one of our boys, and another girl is enjoying a bursary at the Malvern Girls' College.

There must be many of your readers who could allocate or influence further presentations for the use of the Committee. In addition to the 22 cases of various ages for which the Guild is already, wholly or in part, responsible we have applications for help in educational fees and training for a number of small children from the age of 4 upwards, and also from young people who have finished their school course, but urgently need to be helped with their training in some profession or other occupation in order that they may become wage-earning citizens.

The Committee feel that it only requires wide knowledge of these "wants" for the requisite amount of help to be forthcoming from the public, and we therefore beg your readers to voice among their patients the educational work which is being undertaken by the Guild.

We are, Sir, yours faithfully,
MAY BRADFORD,
President.
MARY SCHARLIEB,
Treasurer.
DAISY FRIPP,
Chairman of Committee.
19, Portland-place, London, W. 1, Feb. 5th, 1923.

THE DENTISTS REGISTER.

To the Editor of THE LANCET.

SIR,—Circulars of inquiry as to the accuracy of their addresses have been sent to-day to all persons whose names appeared in the printed Dentists Register for 1922—that is to say, to all persons registered before the passing of the Dentists Act, 1921, under Section 12 (3) of the Dentists Act, 1878, which is as follows :—

> "The general registrar may erase from the Dentists Register the name of a person who has ceased to practise, ... and the general registrar may send by post to a person registered in the Dentists Register a notice inquiring whether or not he has ceased to practise, or has changed his residence ; and if no answer is returned to the inquiry within six months from the posting thereof it shall be lawful to erase the name of that person from the Register."

Any person coming within the above category who does not receive an inquiry in course of post should communicate with me without delay, in order that there may be no risk of the erasure of his name.

I am, Sir, yours faithfully,
NORMAN C. KING,
Registrar.

Dental Board of the United Kingdom, 44, Hallam-street, London, W. 1, Feb. 2nd, 1923.

CŒLIAC DISEASE.

To the Editor of THE LANCET

SIR,—Those interested in the problem of cœliac disease will be grateful to Dr. J. A. Ryle for his letter published in THE LANCET of Jan. 27th. In it he describes, as found during life, a condition of lacteal obstruction due to tuberculous mesenteric glands in a case which showed at the time of operation fatty stools and gave a history of frequent diarrhœic attacks since childhood. This leads him to suggest that cœliac disease may be due to obstruction of the lacteals from tuberculous or other infection. This suggestion is both interesting and novel, for as he truly says, no such dilatation of the lacteals has been noted in any of the very few autopsies on cœliac cases as yet recorded. In my own two autopsies no disease of the mesenteric glands was found, but in both the mesentery was loaded with fat to a degree very unusual in childhood. As Dr. Ryle says, lacteal obstruction would presumably be more obvious during life than after death, and whether such a condition has been hitherto overlooked time will show. At present I do not feel very ready to anticipate that Dr. Ryle's suggestion will turn out to be the correct one.

1. It is difficult to think of any common inflammation other than tuberculous which could give rise to obstruction of the lacteals, and there is certainly no connexion between cœliac disease and tuberculosis. In my two autopsies no tuberculous foci were found in any part of the body, and in a long series of cœliac cases, many of whom were invalids for years, I have never seen overt tuberculosis develop.

2. I am afraid I cannot agree that the pyrexia and enlarged abdomen are caused by an infection. The former is entirely controlled by correct dieting, and the latter is also largely due to a diet too rich in fat and is seen in other types of steatorrhœa—e.g., pancreatic.

3. A feature of Dr. Ryle's case strikes me as most unlike the ordinary cœliac patient—namely, that as adolescence was reached the diarrhœa became worse: I think most will agree that this is just the opposite of what usually happens. May it not be that the tabes mesenterica and the lacteal obstruction, discovered at the age of 23, should be regarded as complicating and not causing the disease of childhood?

This last consideration makes me feel that we may possibly be led astray by what is found after 20 years of illness, and that perhaps the cause of cœliac disease may more safely be searched for by considering the onset of the symptoms in infancy. I happen to have been able to watch three cases from the appearance of the first signs and onwards. The onset of symptoms was abrupt in all, and accompanied teething. Formed stools, perfectly colourless, were passed for three or four days, after which splashes of bright-green pigment appeared in the fæces. Thereafter the appearance of the stools became more approximated to the normal, but from that time onward symptoms of fat-indigestion became evident and the cases settled down into examples of cœliac disease. There are other instances in which there is a more insidious onset which Dr. Ryle's suggestion might be capable of explaining, but I do not see how we can by this means account for such examples as I have quoted. Such cases suggest to my mind that there is a reflex temporary inhibition of the liver which leads to an escape of bile-salts in the fatty stools, which loss cannot be made up.

I am, Sir, yours faithfully,
Harley-street, W., Feb. 5th, 1923. REGINALD MILLER.

"LUNACY REFORM."

A LECTURE TO TONGUE-TIED GUESTS.

To the Editor of THE LANCET.

SIR,—At the "Lunacy Reform" dinner referred to in your last week's issue the position of those guests who were members of the Board of Control and others identified with asylum administration must have been very uncomfortable. It appeared as if they had been invited to a charming feast in order to be lectured to and reproved, without notice and without any chance of reply. Dr. Lomax spoke from 10 to 11 P.M., apparently by invitation, for no suggestion was made from the chair that he was exceeding the time allotted to him. But the most serious side of the matter is the way in which grave accusations were made against mental nurses and apparently accepted by a large number present, upon one-sided statements, and without the persons involved having any opportunity to defend themselves. There is thus created an un-English prejudice against a class of men and women engaged in work for the community admittedly difficult and anxious. The refusal to make these charges before the Board of Control, who have power to examine on oath—or the Ministry of Health Committee which was independent of the Board—is unfair to patients, and it maintains a cruel sustained attack on the nurses. The devotion of mental nurses and their extraordinary patience is known by all those who work in mental hospitals. They work unseen by the public, without encouragement from committees, with little gratitude from patients or their relatives, and in an atmosphere of suspicion which this agitation is accentuating. True, many are badly educated, some are frivolous, a few are harsh and unfeeling, but as a class they do wonderful work for the community. It is abominable that because they are inarticulate they should be slandered.

If the Board of Control refused to investigate accusations, or would not listen to charges and complaints by patients, then a campaign against them might be justified, but I know from experience that they do not turn a deaf ear to complaints that reach them. I am, Sir, yours faithfully,

Feb. 5th, 1923. HOSPES.

*** The false impression of cruelty which may be given by those unqualified to appreciate the meaning of various procedures which they witness is well shown by the following extract from the "Revelations of an Asylum Nurse," which appeared in a weekly paper.

> "There is an old lady whom they call ——, who has a dreadful bedsore on her back ; this they treat with hot grease dropped from a lighted candle—I believe it is what they call an 'amberine' candle ; it seems terrible to think there isn't a less painful way of treating this sore."
>
> "There are several patients here with very bad bedsores, all of which are treated with the candle. I cannot find out just what it is called. Some call it 'Amberine,' some 'Ambrille.'"

The asylum nurse was apparently ignorant that the application of ambrine is painless and that its use proved that the treatment at the hospital in question was well up to date.—ED. L.

Obituary.

JAMES RITCHIE, M.D., B.Sc. Edin., M.A., B.Sc. Oxf., F.R.C.P. Edin.,

IRVINE PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF EDINBURGH.

James Ritchie was born in 1864, son of the Rev. William Ritchie, D.D. He studied arts and medicine in the University of Edinburgh, graduating M.A. in 1884 and qualifying M.B. in 1888. In 1892 he went to Oxford and joined Mr. H. P. Symonds, who died quite recently, in practice. At the same time he worked at bacteriology and gradually laid the foundation of what became the school of pathology of which he was the titular head successively as lecturer, reader, and professor, and always the mainspring and inspiration. Burdon Sanderson gave up the chair of physiology and became professor of medicine in 1895, and it was with his hearty encouragement that Ritchie began the formal teaching of pathology in the University. Regular classes started about 1897. Six or eight or ten men, mostly those who had taken a B.A. in physiology and were stopping up a fifth year to do anatomy with Arthur Thomson, used to meet Ritchie at 4 o'clock three afternoons a week in the two small rooms in the museum assigned for the use of the Regius professor of medicine, and received till dinner time instruction in the theory and practice of pathology under the ideal conditions of intimate personal contact with a great teacher, harrassed sometimes by the cares of practice, but always ready to spend any amount of time helping lame (but generally rather enthusiastic) dogs over the fearful beginnings of practical bacteriology and post mortems. Sanderson gave a few lectures on general pathology and this (with Edwin) was the beginning of the teaching of pathology in Oxford. The thing was so good that it soon expanded into a new department. Ritchie gradually retired from practice as his subject received more ample recognition from the University; he was elected a Fellow of New College in 1902 and it seemed as if Oxford had secured him for good as a regular professor when, to the surprise of most people, in 1906 the attractions of his native heath proved too strong and he returned to Edinburgh as superintendent of the laboratory of the Royal College of Physicians in Forrest-road.

Christmas Island is famous in medical annals as a hot-bed of beri-beri. But the phosphate deposits which brought the Chinese coolies there to live on polished rice also have some pathological interest, for it was a share in the company owning the island which was left to the University of Edinburgh by Mr. Robert Irvine to accumulate till it was adequate for the foundation of a chair of bacteriology. Unexpected prosperity allowed this to be done in 1913, and Ritchie naturally succeeded to the appointment, carrying on through the troublous times of the war and afterwards till the edge of more peaceful progress was in sight. In August of last year he began to have obscure abdominal symptoms, for which no cause could be found until an exploratory operation in October revealed an advanced growth in the tail of the pancreas, from which he slowly went downhill and died on Jan. 28th.

Ritchie will always be remembered as the founder of the study of pathology in Oxford and as the author, along with his lifelong friend Robert Muir, of the famous manual of bacteriology, of which the first edition appeared in 1897, the second in 1899, and others at regular intervals ever since. The characteristics of the book, which have commended it to so many thousands of students of all grades in this country and America, are its sanity and reasonableness. And these are just the qualities which made Ritchie one of the most weighty figures in the history of pathology here during the last 25 years. By what would now be called some sort of inhibition, he was himself almost incapable of carrying out any long laboratory investigation. In the catalogues not more than ten or a dozen papers of original work will be found to his name, and few of them of any great moment. But the work which arose from his personal influence and inspiration and in that atmosphere of the real love of knowledge which there was about him is in quantity very large, and above the average in quality. With a very wide acquaintance with pathology as a whole, he had a soundness of judgment and a standard of performance which many of his pupils look back on as the best part of their education. If a piece of diagnostic bacteriology was worth doing at all, it was worth doing thoroughly, and then he would say "Read Cohnheim."

Ritchie took a prominent part in the foundation of the Pathological Society of Great Britain and Ireland in 1906. He served as secretary and assistant editor from the beginning till 1920, when he succeeded Woodhead as editor. As the journal was printed in Edinburgh, his duties were very far from nominal, and it is wholly due to his continued interest and wise management that the *Journal of Pathology*, bought from the proprietors by a company of members in 1907 when it was at the best a dubious financial proposition, was finally in 1919 handed over as a gift to the Society with a substantial balance in the bank. Through the Society, which has certainly achieved the objects stated in the constitution framed by Ritchie, "to advance pathology and facilitate intercourse between pathologists," and through the journal he exercised a wide influence and always for the good and always on a high level. And here, too, what always stood out was his reasonableness—and his sense of fun and sometimes even of mischief. The University of Edinburgh and the Royal Infirmary, in the management of which in late years he took an increasing share, will miss him in the same way. Anyone in trouble or with a difficulty to solve—in immunity or personal relations or anything else—who knew Ritchie naturally went to him for advice and got the help he wanted. He was one of those cheerfully serene persons who are apt to keep their own bothers in, that they may better help other people with theirs. *Servus servorum pathologiæ.*

A. E. B.

ALEXANDER LEWERS, M.R.C.S., D.P.H.

Dr. Alexander Lewers, the well-known Melbourne physician, who died last September, was the son of one of the pioneers of Creswick, Talbot, Victoria, and received his early education at the grammar school in that town. He afterwards came to London and qualified from St. Mary's Hospital with the English double diploma. Returning to Australia, he became resident medical officer at the Adelaide Hospital for 12 months, and then entered upon general practice at Creswick, being appointed also consulting medical officer to the district hospital. Subsequently, in 1898, he came to England on a post-graduate visit and studied dermatology under the late Sir James Galloway, at the same time obtaining the Diploma of Public Health of the Royal Colleges. He returned to Australia in 1900, and shortly after his return successfully treated the first case of bubonic plague at the quarantine station on Coode Island. Since 1903 he had practised as a physician in Collins-street, Melbourne, commencing also his long connexion with St. Vincent's Hospital as physician to out-patients. This post he held for five years, when he became full physician, and at the time of his death he was senior member of the staff. A clinical school had been established in 1910, at which he became an assiduous teacher, while he was an examiner in clinical medicine at the University of Melbourne. Dr. Lewers was an active member of the British Medical Association, from 1903 to 1914 edited the *Australian Medical Journal*, which was formerly the official organ of the Association, and he was for many years the Australian correspondent of THE LANCET.

Lewers's wide knowledge of medicine, his general literary equipment, and his lucid style made him a very interesting writer. In 1915 he published "Medicine and Meditation," a series of essays touching on such diverse subjects as euthanasia, drink cures, phrenology, eugenics, physical culture, and school inspection. He was editor in chief of the Transactions of the Eighth Session of the Australasian Medical Congress in 1908, which were published in three volumes. Both as a writer and a speaker, Dr. Lewers showed directness and sincerity, and his judgments were always listened to with respect by his confrères. A modest, sincere, and lovable man, his death has deprived the medical profession in Victoria of one of its ablest representatives.

Medical News.

UNIVERSITY OF OXFORD.—The representatives of the University at the conference on the Courses of Instruction Provided by Medical Schools, held at the University of London on Feb. 3rd, were Sir Archibald Garrod, Regius Professor of Medicine, and Dr. Ainley Walker, Dean of the Faculty.—At a congregation held on Jan. 25th the degree of Bachelor of Medicine was conferred on David Sydney Davies, Magdalen College.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—Licences to practise have been conferred upon the following 48 candidates (38 men and 10 women) who have passed the recent final examination and have complied with the necessary by-laws :—

H. C. Beccle, Guy's ; W. C. M. Berridge, St. Thomas's ; F. Beshara, University College ; Kathleen Nevill Blomfield, Royal Free ; W. G. Booth, Guy's ; C. H. Budge, St. Thomas's ; H. G. R. Canning, Guy's ; T. J. Clayton, Charing Cross ; G. S. W. de Saram, St. Bartholomew's ; R. V. Facey, Oxford and St. Thomas's ; G. E. Fisher, Guy's ; S. L. Freedman, University College ; J. H. Gann, London ; Joan Openshaw Geldard, University College ; R. M. Geldart, Cambridge and St. Bartholomew's ; F. Guiver, London ; P. G. Harvey, Guy's ; M. F. Ismail, Middlesex ; H. Jackson, Middlesex ; A. L. P. Jeffery, St. Thomas's ; H. V. M. Jones, St. Thomas's ; J. W. Joule, St. Bartholomew's ; E. Joyston-Bechal, Guy's ; G. Klionsky, St. Bartholomew's ; M. A. Lautre, St. Thomas's ; L. B. Liebster, London ; C. G. Lingford, Middlesex ; Barbara Valentine Lucas, Royal Free ; J. A. Mackay-Ross, St. Bartholomew's ; M. Markiles, Cape and Guy's ; R. G. Morrison, St. Thomas's ; A. L. te W. Naude, Cape and St. Thomas's ; Elizabeth Muriel Nicholson-Smith, King's College ; Judith Evelyn Muriel Ormerod, Royal Free ; E. Orsmond, Cape and Guy's ; A. R. V. Patel, Guy's ; M. K. V. G. Pillai, Madras and London ; Mary Florence Robertine Pitt, London ; Ethel Beatrice Poole, Cardiff and Westminster ; T. P. Rees, Cardiff and St. Bartholomew's ; Emily Virginia Saunders-Jacobs, University College ; P. G. Sedgwick, Guy's ; I. I. A. Shaheed, St. George's ; G. D. Summers, King's College ; S. E. Tanner, University College ; R. W. Taylor, St. Bartholomew's ; Blanchette Thomas, Cardiff and Charing Cross ; and Kathleen Edith Tresilian, London.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—In examinations recently held the following candidates were successful :—

THIRD EXAMINATION.

S. N. Bandyapadhay, Vernon Bell, Eliazer Gelfer, M. L. Hendrie, Elizabeth M. M'Kendrick, Jonathan Johan du Pre le Roux, James Ryan, Hariprasanna Sen, Soo Hock Tan, J. S. Whyteside, and A. C. Young.

Materia Medica.—Trevor Hughes, C. A. Basil, Mollie F. Churcher, A. J. M. Findlater, P. J. Badenhorst, R. D. Jones, and E. G. Douglas.

Pathology.—Malcolm M'Crimmon.

FINAL EXAMINATION.

David Gold, Thomas Cowie Hilston Neil, Charles J. B. Fox, James M. Crombie, Ernest Brazao, Annie Fleming Perry, Hilda Page, Johannes Jacobus Malan, Katherine M. Cellan-Jones, Bernard M'Laughlin, John B. Rodrigo, Ian S. R. Bain, and El Saled et Goharg Sheir.

Medicine.—James S. Bizzett, Edward T. Hall, John J. Mann, James H. Murrell, Ronald M'Donald M'Kinnon, and Charles C. L. Spurring.

Midwifery.—James S. Bizzett, Donald G. Coutts, John J. Mann, James H. Murrell, and Charles C. L. Spurring.

Medical Jurisprudence and Public Health.—John C. Colvin, Donald G. Coutts, James G. Currie, Jitendranath Dey, David K. Fisher, Meyer Goldberg, Charles M. Hinds, Owain ap Vychan Jones, Richard F. Kerr, Lawrence A. Moody, W. Melrose, Archibald Menzies, John Patrick T. Mills, James G. O'Kieffe, George Macgregor Rose, J. J. du Pre le Roux, Robert D. Scorgi, and Hariprasanna Sen.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society will be held at the Miller General Hospital, Greenwich, to-day, Friday, Feb. 9th, at 8.45 P.M. Dr. W. H. Payne, the President, will occupy the chair, and Dr. John Parkinson will give an address on Palpitation.

ROYAL INSTITUTION.—The Friday evening discourse on Feb. 16th will be delivered by Prof. A. V. Hill on Muscular Exercise.

RONTGEN SOCIETY.—The ordinary general meeting has been postponed to Feb. 23rd, when a joint meeting will be held with the Physical Society, the subject for discussion being the Measurement of X Rays.

TWO MILLION SHILLINGS FUND FOR MANCHESTER HOSPITALS.—It is proposed to lighten the financial burdens of the Manchester and Salford hospitals by a scheme for raising £100,000. The scheme is to be called the Lord Mayor's Two Million Shillings Fund, and the Lord Mayor of Manchester proposes to open the fund in March, the scheme being run by a representative committee. The local infirmaries have a debit balance of £63,000.

Prof. E. H. Starling has been appointed by the President and Council of the Royal Society to be the first Foulerton Professor, and will carry on his researches at University College, London. Dr. H. W. C. Vines has been appointed to a Foulerton Research Studentship and will work in the medical school of the University of Cambridge. The conditions of the bequest under which these appointments were made have already been detailed in THE LANCET (1922, ii., 190).

Prof. G. Elliot Smith gave the Montgomery lecture on the Movements of the Eyes before the Royal College of Surgeons in Ireland on Jan. 29th. On the following day he lectured before the Royal Zoological Society on Mythical Monsters. Both lectures were delivered in the Hall of the Royal College of Surgeons, and were well attended. On the evening of the 29th Sir William Wheeler, the President of the College, entertained Dr. Elliot Smith and a large company of guests to dinner at the College.

THE LATE DR. W. E. S. SCOTT.—William Edward Sawers Scott died on Jan. 31st at the age of 62. Dr. Scott was a graduate in medicine of the University of Edinburgh, becoming M.B. in 1885 and M.D. in 1889, and was also a B.Sc. Manch. He was one of the best-known medical men in the Withington district of Manchester, where he was in practice for over 30 years. During the war he served in France as a captain in the R.A.M.C. Dr. Scott was an hon. surgeon of the Clinical Hospital for Women and Children, and hon. secretary of the Manchester and Salford Sanitary Association.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART : *Post-graduate Instruction.*—The following syllabus of a special course of lectures, to be given on Thursdays at 5.30 P.M., has been issued : Feb. 15th, Cardiac Arrhythmias, by Dr. F. W. Price ; Feb. 22nd, Heart Attacks, by Dr. John Parkinson ; March 1st, Heart Disease and Occupations, by Dr. R. O. Moon ; March 8th, Some Points in the Treatment of Heart Disease, by Dr. P. Hamill ; March 15th, the Differences in the Circulation in Aortic and Mitral Disease, by Sir S. Russell-Wells, M.P. ; March 22nd, the Toxic Heart, by Dr. J. Strickland Goodall ; March 29th, the Diagnosis and Drug Treatment of Auricular Fibrillation, by Dr. B. T. Parsons-Smith. The clinical practice of the hospital and appointments as clinical assistants are open to members of the course. A fee of £2 2*s.* a month, or £5 5*s.* for three months, is charged. All inquiries should be addressed to the Dean, Dr. B. T. Parsons-Smith, at the hospital, Westmoreland-street, Marylebone, London, W.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.—The next annual congress of the Society will be held on April 26th, 27th, and 28th at the Royal Society of Medicine, 1, Wimpole-street, London, W. 1, under the presidency of Dr. A. Maitland Ramsay. The arrangements will be as follows :—April 26th, Morning session : President's opening address. Papers by Mr. R. Affleck Greeves and by Mr. R. Foster Moore on Series of Consecutive Cases of Cataract Extraction by Barracquer's Method. Afternoon session : Discussion on the Disorders of the Blood and their Ophthalmological Manifestations, to be opened by Sir Humphry Rolleston, Sir Frederick Andrewes, F.R.S., and Dr. W. C. Souter. In the evening the Bowman lecture will be delivered by Prof. George E. de Schweinitz on Certain Ocular Aspects of Pituitary Body Disorders, Mainly Exclusive of the Usual Central and Peripheral Hemiopic Field Defects. On April 27th, in the morning, a discussion on the Diagnostic Significance of Proptosis will be opened by Mr. Wilfred Trotter, Mr. Herbert Fisher, and Dr. Angus MacGillivray. In the afternoon a visit will be paid to the London Hospital, Whitechapel. In the evening a demonstration will be given by members. On April 28th Dr. Angus MacGillivray will read a paper on Enucleation of the Eyeball under Local Anæsthesia. Members desirous of taking part in the congress are requested to communicate as soon as possible with Mr. R. Foster Moore, 91, Harley-street, London, W. 1.

British Industries Fair.—The Fair to be held under the auspices of the Department of Overseas Trade at the White City, Shepherd's Bush, London, from Feb. 19th to March 2nd, will again this year give prominent place to chemicals, drugs, medical and surgical appliances, and scientific instruments.

Small-pox.—A case of small-pox was reported at Clitheroe last week. The patient was removed to Blackburn isolation hospital and the sources of infection have been traced. There are 27 cases in the coal-mining district of Clowne, near Chesterfield, Derbyshire. It is stated that none of the sufferers had been vaccinated.

Royal Institute of Public Health. — The annual congress will be held in Scarborough from May 16th to 21st, Lord Riddell presiding. The congress will be conducted in the following sections under the presidents shown: (1) State Medicine and Municipal Hygiene, Sir William Middlebrook; (2) Naval, Military, Air, and Tropical Diseases, Lieut.-General Sir Arthur Sloggett; (3) Bacteriology and Bio-Chemistry, Dr. Fred. W. Twort; (4) Women and the Public Health, Lady Dorothy Wood; (5) Industrial Hygiene, Sir Lynden Macassey.

The late Dr. G. A. W. Spear.—Dr. George Arthur Whitworth Spear died at his residence in Pulborough on Jan. 27th, at the early age of 47. The son of Dr. John Spear, for many years H.M. Inspector to the Local Government Board, he was educated in France and at Oxford, qualifying L.R.C.P. and M.R.C.S. from St. Bartholomew's Hospital in 1899. After practising at Fittleworth Dr. Spear moved, in 1909, to Pulborough, where, besides holding a number of public appointments, he had an extensive practice. He saw service during the war with the 29th Division and with the 17th General Hospital at Alexandria. He married in 1903 a daughter of Mr. Edmund Ashton, of Hatfield, Herts, by whom he had two sons and a daughter.

Donations and Bequests.—Mrs. Mary Sellars Taylor has left a legacy of £1000 to endow two cots at the Bolton Infirmary, and the same institution has received £1000 from the executors of the late Mrs. Mary Ann Hall, £500 from Mrs. Margaret Knowles for the special appeal fund, and £500 from Mr. and Mrs. George Barnes. The house-to-house collection in Bolton and Farnworth realised £1067, and that at the places of worship £1111.—Mr. Samuel Gamble of Fallowfield, Manchester, left £1000 to the Medical Department of the Baptist Missionary Society, and £200 to the Manchester and Salford Women's Christian Temperance Association.—A sum of £20,000 has been given by Mrs. Marryat, sister of the late Sir James Caird, to Dundee Royal Infirmary, for the purpose of building and equipping two operating theatres and a central electrical department.

Norfolk and Norwich Hospital.—The quarterly report of this institution shows that the in-patients admitted during the last quarter of 1922 had been 778, a slight falling off from the numbers admitted in the corresponding quarter of 1921. The daily average number of in-patients had, however, been 261 as against 237 in 1921. There were 703 operations performed, and 1084 new cases treated in the out-patient department; 1520 accidents and casualties were treated. In the corresponding period of 1921 these figures were: operations, 697; out-patients, 874; accidents, &c., 1587. The total grant from the Norwich Hospitals Sunday and Saturday Fund for the year 1922 amounted to £17,880, an increase of £6600 over the amount received in 1921; this was due to the wonderful success of the contributory scheme. A handsome donation of £1000 had been received from Mrs. C. S. Robinson, for the endowment of a bed in memory of her husband, who was killed in the war. At the last meeting of the board of governors a suggestion was made that some friends of the hospital might like to defray the cost of a new operating table and the installation of a new form of lighting for one of the theatres. Within three days of the meeting three offers to cover the expenditure were received, and the first offer, coming from a friend who wished to be anonymous, was gratefully accepted. Mr. S. H. Burton, consulting surgeon, stated that the operating table was now in full working order, and that the light would soon be installed. The great point about the light was that it was concentrated by parallel rays from above, so that the operating area was well lit and there were no shadows. The X ray and pathological departments were now in full working order. The equipment, which cost about £500, came out of the Red Cross grant, and did not affect the general funds of the hospital. The vacancy in the pathological department, caused by the resignation of Dr. E. W. Todd, has been filled by the appointment of Dr. D. S. Brough. Owing to the increase in the work of this department and the impossibility of obtaining the services of an honorary assistant who would be able to give the necessary time to the work, the assistant pathologist is now a part-time salaried officer.

The Services.

ROYAL ARMY MEDICAL CORPS.

THE following were the successful candidates for commissions in the Royal Army Medical Corps at the competition held in London last month: H. A. Gilkes, M.B., Ch.B Oxf., Oxford University, St. Bartholomew's Hospital; R. Murphy, B.A., M.B., B.Ch., B.A.O. Dub., Trinity College, Dublin; F. C. H. Sergeant, M.B., Ch.B. Liverp., Liverpool University; W. L. S. Cox, M.R.C.S. Eng., L.R.C.P. Lond., University College Hospital.

Maj. J. E. H. Gatt retires on ret. pay.

Maj. E. B. Booth retires on ret. pay and is granted the rank of Lt.-Col.

Maj. D. de C. O'Grady retires receiving a gratuity.

Temp. Capts. H. J. Pickering (granted the rank of Maj.) and T. A. Davies (retaining the rank of Capt.) relinquish their comms.

ROYAL HOSPITAL, CHELSEA.

Capt. R. R. Thompson to be Deputy Surgeon, vice Maj. R. E. Todd, vacated.

MILITIA.

Capt. N. H. S. Maelzer relinquishes his commn. and retains the rank of Capt.

TERRITORIAL ARMY.

The undermentioned relinquish their commns. and retain their rank except where otherwise stated: Capts. R. C. Elmslie (Bt. Maj.) (granted the rank of Maj.), R. E. Apperly, J. E. Adams, I. G. Back, S. Hastings, H. B. Weir, R. V. Slattery (granted the rank of Maj.), and G. E. O. Williams; Maj. D. G. Hall; Capts. J. F. Gaskell, E. C. Crichton, R. C. Canney, and A. S. Daly. Sanitary Companies: Capt. P. A. Galpin.

The following relinquish their commns.: Maj. A. T. Mulhall (granted the rank of Lt.-Col.); Capts. H. R. Dive (granted the rank of Maj.), G. H. Kirby, C. A. Robinson, and D. J. Bedford (all retaining their rank).

Capt. H. Drummond to be Maj.

Second Lt. M. H. Summers, from 8th Bn., Middlesex R., T.A., to be Lt.

General Hospitals: The undermentioned offrs., having attained the age limit, are retired, and retain their rank except where otherwise stated: Lt.-Col. A. G. Barrs; Majs. T. W. Griffith (Bt. Lt.-Col.) (granted the rank of Lt.-Col.), J. Phillips, W. Thompson (granted the rank of Lt.-Col.), R. L. Knaggs, H. S. Walker, and J. K. Jamieson; Capts. R. A. Veale (granted the rank of Lt.-Col.), S. S. Whillis, H. H. Markham, J. W. Heslop, S. McDonald, G. C. Hayes, S. W. Daw, D. Seaton, G. P. Anning, F. J. Stansfield, C. Oldfield, L. A. Rowden, H. H. Greenwood, W. H. Brailey (granted the rank of Maj.), A. Ellison, and F. H. Humphris (granted the rank of Maj.).

Capts. N. Hodgson (granted the rank of Maj.), and V. Z. Cope (retaining the rank of Capt.) relinquish their commns.

The undermentioned from School of Instruction, to be Div. Adjt.: Maj. J. R. Yourell, 46th (North Mid.) Divn.; and Capt. C. Popham to be Div. Adjt., 51st (High.) Div., T.A., vice Capt. H. W. L. Allott, vacated.

TERRITORIAL ARMY RESERVE.

Lt.-Col. T. H. Forrest, from Genl. List, to be Lt.-Col.

Capt. W. Brown, from Genl. List, to be Lt.-Col.

Capt. A. Findlater relinquishes his commission and retain the rank of Capt.

ROYAL AIR FORCE.

W. B. Stott is granted a short service commission as a Flying Officer.

INDIAN MEDICAL SERVICE.

Lt.-Cols. J. H. McDonald and A. W. R. Cochrane to be Cols.

The King has approved the retirement of Lt.-Col. E. H. B. Stanley, Maj. and Bt. Lt.-Col. R. S. Kennedy, and Maj. D. M. C. Church.

DEATHS IN THE SERVICES.

Deputy Inspector-General Alfred Gideon Delmege, R.N., Hon. Surgeon to the King, died on Feb. 2nd, at Blackheath, in his seventy-seventh year. He served with the first detachment of Marines sent out to Cape Coast Castle in the Ashanti War, 1873 (Ashanti Medal), and was in the *Bacchante*, 1879–1882, when the Princes Albert Victor and George of Wales (now His Majesty) cruised round the world. He was awarded the M.V.O. for professional services during the illness of King Edward (then Prince of Wales) in 1898, and had previously served in the Royal Yacht *Osborne*.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, London, W.

THURSDAY, Feb. 15th.—Papers to be read :—E. R. Speyer : Researches upon the *Larch Chermes* (Cnaphalodes strobilobius Kalt) and their bearing upon the Evolution of the *Chermesinæ* in General. (Communicated by Prof. G. C. Bourne.) G. V. Anrep : The Irradiation of Conditioned Reflexes. (Communicated by Prof. E. H. Starling.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Feb. 12th.

WAR : at 5 P.M. (Tea will be served at 4.30 P.M.)

Discussion on the Coöperation between the Members of the Profession and the Medical Services of the Armed Forces in Peace and During War.

Short papers on this subject will be read by Surg.-Capt. A. Gaskell and Surg.-Capt. R. J. McKeown.

Air Commodore D. Munro will open the Discussion, followed by Major-General C. E. Pollock, Sir Crisp English, and others. Speakers will be limited to 10 minutes.

The subject of these papers and the discussion which will follow should be of great interest to all medical men, and the President of the Section (Sir John Goodwin) hopes that there will be a very large attendance. Visitors are invited, whether Members of the Section or not.

Tuesday, Feb. 13th.

THERAPEUTICS AND PHARMACOLOGY : at 4.30 P.M.

Papers :

Prof. A. J. Clark : The Scientific Basis of Non-specific Protein Therapy.

Short Paper :

Dr. H. Blumgart (introduced by Dr. H. H. Dale) : The Treatment of Diabetes Insipidus by Intranasal Spraying of Pituitary Extract.

PSYCHIATRY : at 8.30 P.M.

Paper :

Dr. Kinnier Wilson : Involuntary Laughing and Crying.

Wednesday, Feb. 14th.

SURGERY : SUB-SECTION OF PROCTOLOGY : at 5.30 P.M.

Short Paper :

Mr. P. Lockhart-Mummery : New Method of Treating Ischio-rectal and other Abscesses.

Cases and Specimens : Cases and specimens will be shown by :—

Sir Charles Gordon-Watson.

Mr. W. Ernest Miles : (1) Specimen of Adenomyoma of the Rectum. (2) Papilliferous Carcinoma Intussuscepted into the Rectum.

Mr. Lockhart-Mummery : Adenomyoma of the Rectum removed by Abdomino-perineal Excision of the Rectum.

Mr. Shorney Webb : Submucous Lipoma of Transverse Colon causing Intussusception.

Mr. Gabriel : Polyp associated with Stricture of Rectum.

Mr. Percival P. Cole : (1) Colon from case of Dysentery, showing Multiple Perforations. (2) Carcinoma of the Pelvic Colon with Vesico-colic Fistula.

N.B.—Will Members desiring to show specimens kindly notify Mr. Percival P. Cole, 15, Harley-street, W. 1.

Thursday, Feb. 15th.

DERMATOLOGY : at 5 P.M. (Cases at 4.30 P.M.)

Cases : The following will be shown by—

Dr. Bunch : (1) Anomalous Tuberculide. (2) Trichorrhexis Nodosa.

Dr. Arthur Whitfield : (1) Case for Diagnosis. (2) Acarus, from case of Scabies Infected by a Dog.

Dr. J. H. Sequeira : Angeiomatous Granuloma (Kaposi). (Two cases.)

Dr. A. M. H. Gray : (1) Kaposi's "Sarcoma." (2) Rodent Ulcer under Treatment by Arsenic Paste.

Other cases will be shown.

Members of this Section are cordially invited to attend the Meeting of the Section of Tropical Diseases and Parasitology announced for Monday, March 5th.

Friday, Feb. 16th.

OTOLOGY : at 5 P.M. (Cases at 4.45 P.M.)

Mr. G. J. Jenkins will give a Preliminary Communication on the subject of Osteitis Deformans and Otosclerosis.

Cases and Specimens :

Sir James Dundas-Grant will show a case of Nerve Deafness and Vertigo with Unusual Vestibular Reactions (previously shown). Neurological Report from Dr. Worster-Drought.

Other cases will be shown.

ELECTRO-THERAPEUTICS : at 8.30 P.M.

Paper :

Prof. Philippson (Brussels) : High-Frequency Currents Applied to the Study of Cellular Physiology.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.

THURSDAY, Feb. 15th.—8.15 P.M., Lieut.-Colonel Sir Leonard Rogers : The World Incidence of Leprosy in Relation to Meteorological Conditions and Its Bearing on the Probable Mode of Transmission. (Preceded at 7.45 P.M. by a demonstration of maps illustrating the paper.)

Lantern Slide Demonstration by Mr. C. F. Massy Swynnerton on the Relation of Some East African Tsetses to the Vegetation.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, Feb. 12th.—11 A.M., Mr. Maingot : Surgical Ward Cases. 12 noon, Mr. Simmonds : Applied Anatomy. 2 P.M., Mr. Addison : Surgical Wards.

TUESDAY.—10.30 A.M., Dr. Paterson : Demonstration of Medical Cases. 12 noon, Dr. Burrell : Chest Cases. 2.30 P.M., Mr. Tyrrell Gray : Surgical Wards.

WEDNESDAY.—10 A.M., Dr. Saunders : Medical Diseases of Children. 12 noon, Dr. Burnford : Pathological Demonstration. 4 P.M., Mr. D. Armour : Suppuration of the Scalp and Skull.

THURSDAY.—10 A.M., Dr. Grainger Stewart : Neurological Department. 12 noon, Mr. Simmonds : Demonstration of Fractures. 4 P.M., Mr. Dunhill : Some Problems of the Thyroid and Parathyroid Glands.

FRIDAY.—12 noon, Dr. Flett : Radiology. 2 P.M., Mr. Banks-Davis : Diseases of Throat, Nose, and Ear. 3 P.M., Mr. Sinclair : Surgical Cases.

SATURDAY.—9 A.M., Dr. Burnford : Bacterial Therapy. 10 A.M., Dr. Saunders : Medical Diseases of Children. 10.30 A.M., Mr. Maingot : Surgical Pathology.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

TUESDAY, Feb. 13th.—4.30 P.M., Dr. Hector C. Cameron : Demonstration of Ailments in Children.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE : JAN.-MARCH, 1923.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Feb. 12th.—2 P.M., Out-patient Clinic : Dr. Hinds Howell. 3.30 P.M., Lecture :—The Control of Ocular Movements : Mr. Leslie Paton.

TUESDAY, Feb. 13th.—2 P.M., Out-patient Clinic : Dr. Grainger Stewart. 3.30 P.M., Lecture :—The Tendon Jerks and Superficial Reflexes in Diagnosis : Dr. Risien Russell.

THURSDAY, Feb. 15th.—2 P.M., Out-patient Clinic : Dr. Kinnier Wilson. 3.30 P.M., Lecture :—Painful Affections of the Upper Limb and Their Treatment : Dr. Grainger Stewart.

FRIDAY, Feb. 16th.—2 P.M., Out-patient Clinic : Dr. Gordon Holmes. 3.30 P.M., Lecture :—Cerebral Diplegia : Dr. Collier.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

NEURO-PATHOLOGY.

MONDAY, Feb. 12th.—12 noon, Pathology of the Neuron : Dr. J. Godwin Greenfield.

N.B.—A Course of Lectures in the Anatomy and Physiology of the Nervous System will be given if there are sufficient entries for it.

The fee for the whole Course, including Anatomy and Physiology, is £12 12*s.*, but these Lectures may be taken separately for a fee of £4 4*s.* Course without Anatomy and Physiology Lectures will be £10 10*s.* Any part of the Course may be taken separately at a special fee. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.

C. M. HINDS HOWELL, Dean of Medical School.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, Marylebone, W.

POST-GRADUATE COURSE : February and March.

THURSDAY, Feb. 15th.—Dr. F. W. Price : Cardiac Arrhythmias.

HOSPITAL FOR SICK CHILDREN, Great Ormond-st., W.C.

THURSDAY, Feb. 15th.—4 P.M., Dr. Hutchison : Infantilism and Allied Disorders of Development.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

THURSDAY, Feb. 15th.—5 P.M., Dr. W. Griffith : The Skin Eruptions of Syphilis.

MANCHESTER ROYAL INFIRMARY, POST-GRADUATE LECTURES.

TUESDAY, Feb. 13th.—4.15 P.M., Dr. F. E. Tylecote : The Part Played by Vascular Spasm in Disease.

FRIDAY, Feb. 16th.—4.15 P.M., Mr. J. Morley : Applied Anatomy of the Gastro-Intestinal Tract.

ST. MARY'S HOSPITALS, MANCHESTER. POST-GRADUATE LECTURE (at Whitworth-street West Branch).

FRIDAY, Feb. 16th.—4.30 P.M., Dr. J. F. Ward : Albuminuria in Childhood.

SALFORD ROYAL HOSPITAL. POST-GRADUATE LECTURE.

THURSDAY, Feb. 15th.—4.30 P.M., Dr. Corsar Sturrock : Epliepsy.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
WEDNESDAY, Feb. 14th.—4 P.M., Dr. A. H. Gosse: Public Health Aspects of Pulmonary Tuberculosis.

Appointments.

HALL, A. W., L.R.C.P., M.R.C.S., has been appointed House Surgeon to the Kidderminster Infirmary.

Vacancies.

For further information refer to the advertisement columns.

Barnsley, Beckett Hospital.—Jun. H.S. £200.
Bradford Royal Infirmary.—Two H.S.'s. £150.
Cambridgeshire Mental Hospital, Fulbourn, near Cambridge.—Second Asst. M.O. £350.
City of London Hospital for Diseases of the Chest, Victoria Park, E.—Asst. M.O. £100.
City of London Maternity Hospital, City-road, E.C.—R.M.O. £100.
Derbyshire Education Committee.—Asst. School M.O. £600.
Derbyshire Hospital for Sick Children.—Res. M.O. £150.
Gloucestershire Tuberculosis Institution, Standish House, Stonehouse, Glos.—Asst. R.M.O. £300.
Ipswich, East Suffolk and Ipswich Hospital.—H.S. £125.
Kensington, Fulham, and Chelsea Hospital, Earl's Court, S.W.—Clin. Asst. £30.
Liverpool Education Authority.—Sen. Asst. Sch. M.O. £750.
Liverpool, Royal Southern Hospital.—Res. Cas. O. £150. Also Two H.P.'s and Three H.S.'s. Each £100.
London County Mental Hospital Service.—Seventh Asst. M.O. £449.
Manchester Children's Hospital, Pendlebury.—Res. M.O. £80.
Manchester, Whitworth Park Hospital.—Res. Surg. O. £250. Also H.S.'s. £100 each.
Nottingham General Dispensary.—Res. Surg. £300.
Rosslynlee Asylum, Rosslyn Castle.—Asst. M.O. £300.
Rotherham Hospital.—Jun. H.S. £150.
Royal Eye Hospital, St. George's Circus, Southwark, S.E.—Hon. Asst. S. Also Clin. Assts.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. P. to Skin Dept.
Southampton, Royal South Hants and Southampton Hospital.—Jun. H.S. £150.
St. Paul's Hospital for Skin and Genito-Urinary Diseases, Red Lion-square, W.C.—Res. M.O £300.
Swansea General and Eye Hospital.—H.P. £200. Also H.S. for Ophthalmic, &c., Depts. £200.
Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Cas. Sorting O. and Anæsth. £150.
West End Hospital for Nervous Diseases, Regent's Park, N.W.—Senior H.P. £150. Also Jun. H.P. £100.
West Hartlepool, Cameron Hospital.—H.S. £200.
Wolverhampton and Staffordshire General Hospital.—H.S. £200.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Ventnor (Isle of Wight), Llanwrtyd Wells (Brecon), Honiton (Devon), and Knighton (Radnor).

Births, Marriages, and Deaths.

BIRTHS.

FOULKES.—On Feb. 4th, at Exeter, the wife of Richard K. Foulkes, of a daughter.

GOODWIN.—On Jan. 28th, the wife of Cecil G. R. Goodwin, L.R.C.P. (Barrasford Sanatorium, Northumberland), of a son.

MARRIAGES.

BLAIR—WOODHOUSE.—On Jan. 17th, at All Saints' Church Hull, Robert Bertram Blair, M.B., F.R.C.S. Edin., to Frances Mary, fourth daughter of Dr. Herbert Woodhouse, C.B.E., J.P., and Mrs. Woodhouse, of Roos in Holderness, and The Park, Hull.

BROWN—EMERY.—On Feb. 5th, at the Golders Green Wesleyan Church, Oscar F. Brown, M.A., B.Sc. Oxf., to Doris Kathleen Emery, M.R.C.S., L.R.C.P.

MACGILLIVRAY—CUSHNY.—At St. Cuthbert's Church, Edinburgh, on Feb. 2nd, 1923, by the Rev. P. Dunn, D.D., Dr. Alex. G. MacGillivray, of Southwaite, Cumberland, elder son of Dr. C. W. MacGillivray, to Helen Ogilvie Cushny, only daughter of Prof. Cushny, University of Edinburgh.

DEATHS.

COGILL.—On Feb. 2nd, at Seaton, Devon, Harry Cogill, M.R.C.S., L.R.C.P., of Queen Anne's-gardens, Bush Hill Park.

DELMEGE.—On Feb. 2nd, at Westcombe Park-road, Blackheath, Deputy Inspector General A. G. Delmege, R.N., M.V.O., K.H.S., aged 76.

PYWELL.—On Jan. 30th, at a nursing home at Ewell, Percy Dodd Pywell, M.R.C.S., L.R.C.P., late of York-road, S.E.

SINCLAIR.—On Jan. 29th, at The Moorings, Paget-road, Ipswich, Walter William Sinclair, M.B., aged 54.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

DEPOSIT CONTRIBUTORS TO NATIONAL HEALTH INSURANCE:

DRAWBACKS OF THE SYSTEM.[1]

BY HAROLD S. BEADLES, M.R.C.S. ENG.,
SECRETARY OF THE WEST HAM LOCAL MEDICAL AND PANEL COMMITTEES; AND CHAIRMAN TO THE WEST HAM INSURANCE COMMITTEE.

IN introducing the subject of the position in National Health Insurance of that class of the insured community known as the deposit contributors I desire to keep prominently before our minds the fact that the National Insurance Act is claimed to be "An Act to provide for insurance against loss of health and for the prevention and cure of sickness." The inauguration of such a social reform as National Health Insurance, influencing as it did practically every phase of Great Britain's communal life, was necessarily complex. The early administration of the measure was not rendered less difficult by the effort made in the construction of the Act of 1911 to legislate for the then known varying circumstances of employed persons, whereby over 20 separate classes of insured persons were provided for. At the date of this conference material improvement has been brought about by piece legislation in the direction of simplification. The most important class of "employed" person remaining to be dealt with, however, is the deposit contributor class.

Position of the Deposit Contributor.

Deposit contributors and their employers pay the same contributions as those paid by and in respect of members of approved societies; but the contributions are carried into a separate fund and individual account is kept of the sums paid in respect of each contributor. The first charge on a deposit contributor's account is his share of the cost of medical benefit and administration, and this charge for the current and next benefit half-year must be met before any payment for other benefits can be made. Payment of benefit depends in individual cases upon the amount standing to the person's credit. Thus the title of "insurance" applied to the contributions extracted from, and the benefits set aside for, the people of this group is a gross misnomer, and the intention announced in the preamble of the National Health Insurance Act is defeated so far as the deposit contributor is concerned.

The limitations indicated above and the consequent suspension from benefits upon exhaustion of credit, and subsequent reinstatement to medical benefit upon acquisition of contributions, tends to render the administration of medical benefit to deposit contributors a matter of considerable complexity, involving an undue volume of administrative work by the Government department, the insurance committees, and the insurance practitioners, since, in comparison with members of approved societies who can, within certain limits, draw as required on a common fund built up by the contributions of all the other members, and who, once in the society of their choice, with few exceptions remain there—the suspensions from, and other operations in respect of, medical benefit and reinstatements are proportionately more numerous than those of society members. The normal changes in an insurance practitioner's list due to alterations of status of approved societies' members cause the practitioner considerable difficulty and sometimes doubt, but his difficulties and doubts are multiplied by the transfers to societies and the variation in the status of deposit contributors.

From this aspect the subject is of considerable interest to insurance practitioners, insurance committees, and approved societies; every possible effort should be exerted by all concerned to reduce as far as possible the administrative details connected with National Health Insurance. But how does the system affect the patient? I have seen it stated that deposit contributors form "a group demanding prior consideration of its needs as being most urgently in want of qualified medical assistance and financial support." The author of these words probably accepted without question the dictum that the bulk of "employed persons" who did not join approved societies were derelicts in health. It is possible that the facts will prove otherwise. I believe that in 1911 and 1912, when certain approved societies were "signing on" members under the National Health Insurance scheme, practically no regard was had to the physical condition of the proposer. We know that the "application for admission" form required answers to questions on that point, and that later, when claims were received by some societies, they proceeded to investigate the application forms with a view to the possibility of evading sickness and other benefits liabilities by the discovery of false declaration of physical conditions; but, generally speaking, societies took in and retained all and sundry without making ill-health an insuperable bar to membership.

---

[1] A paper introducing a discussion at the Guildhall Conference on Medical Service under the National Health Insurance Acts.

Reasons for that Position.

I suggest, therefore, that there are other equally weighty reasons why contributors remained and still remain under the "deposit" arrangements. Consequently I would set the principal reasons down in the following order of precedence: (1) Ignorance and ineptitude: for example, the notion held by some persons that by not joining approved societies they retained complete independence, or the view held by other persons that by contributing to State insurance through the Post Office or as "Post Office contributors" (as they were at one time called) they secured a greater measure of State support and guarantee. (2) The influence upon some persons of the knowledge that upon death or emigration, deposit contributions were partially recoverable by the contributor or by the next-of-kin, and that this power of recovery did not rest with an approved society member or his representative. (3) Ill-health causing inability, after the first rush of applications for membership, to secure admission to approved societies, or if such admission had by chance been secured, causing expulsion from approved societies.

Experience in a Single Area.

I cannot venture to say what proportion of deposit contributors is now represented by persons actuated by one or other of these three causes. Possibly a fairly clear idea on this subject might be forthcoming from an examination of the detailed records in the possession of the Controller of National Health Insurance. I have not had time to obtain this information, and I am compelled to base my observations upon the limited experience of the West Ham area, with which I am intimately connected. There is little doubt, I think, that during the first year or two of the operation of the Act the larger proportion of deposit contributors represented persons who, though good lives, continued as such through sheer ignorance, and that between then and now this proportion has gradually undergone diminution. I think the experience of my own area furnishes an excellent criterion for the country as a whole. Here we had, in 1913, some 4450 deposit contributors on register as entitled to benefits. By January, 1923, this number had been reduced to 2200. The factors operating in the net reduction of 2250 were: (*a*) Total new entrants as deposit contributors 8950; (*b*) suspensions from benefit (of which it is fairly certain that a considerable number represent undetected transfers to societies) 6800 gross, and after deducting 2100 reinstatements 4700 net; (*c*) transfers to approved societies 1500; (*d*) enlistments 300; (*e*) deaths 100; (*f*) removals abroad, 150. Total dropped out 6750. Thus, of the total number of deposit contributors registered for the area 52 per cent. have been suspended without recovery for various reasons, the principal reason being assumed to be that of undetected transfers to societies; 17 per cent. have, without doubt, transferred to societies; 6 per cent. have died, emigrated, &c., whilst 25 per cent. still remain deposit contributors Of the 2250 deposit contributors still on our register 1200, or 53 per cent., have chosen and are on doctors' lists, while 1050, or 47 per cent., have not selected doctors; as compared with 78 per cent. and 22 per cent. respectively for the whole of the insured persons of the area.

Problem of Extension of Full Insurance to Deposit Contributors.

The question now arises, what is to be done? Are deposit contributors to be allowed to drift on, causing unnecessary confusion in health insurance for an indefinite period, in the hope that they will in the end disappear of themselves, or shall they be brought into line forthwith? As I have already shown, the problem has so far as a considerable proportion of the original deposit contributors is concerned (estimated at 50 per cent. in my own area) solved itself by transfers to approved societies. I am inclined to think that but for the war and subsequent unemployment difficulties, this form of absorption would have been far greater; be that as it may, the advisability of placing all insured persons upon an equal footing as regards insurance remains a vital problem.

I contend that full insurance should be extended to deposit contributors whether the majority be healthy or unhealthy persons. If the majority represent good insurance subjects, their surplus of contributions should be made available for the assistance of their less fortunate fellows. On the other hand, if the majority represent bad insurance subjects, then they should be given the maximum measure of security purported to be given by the insurance laws.

Suggested Methods of Dealing with the Problem.

The three methods of dealing with the group which seem to me to be the most feasible are presented as follows: (1) Complete nationalisation of health insurance—that is, the construction of a scheme whereby all persons shall pay equal contributions for which they shall be entitled to receive equal benefits; (2) allocation of all deposit contributors to the present approved societies; and (3) constitution of a separate approved society or association for persons who do not join an approved society within a limited time.

With regard to the first method, the complete nationalisation of National Health Insurance is undoubtedly the only way to attain the ideal held forth in the preamble of the 1911 Act. On the other hand, the present approved society system is firmly established and working for good or ill, and transition to the territorial system would present difficulties and initial expense which might preclude any attempt in that direction at the present time of financial and economic strain. With regard to the second alternative, I suggest there should be certain conditions attached to any allocation of deposit contributors to approved societies. Of them I would mention as the most important: (*a*) that each deposit contributor should be given notice of power to select a society within a given time; (*b*) that deposit contributors who have not exercised their right within such given time should be allocated to societies selected by the Ministry of Health; (*c*) that the right of approved societies to refuse members upon health grounds should be withdrawn; and (*d*) that the surpluses and deficiencies of all approved societies in the Kingdom should be pooled for the benefit or otherwise of all persons insured under the National Insurance Acts. With regard to the third and last alternative, I suggest that this is at the moment nearest to the solution of the problem. Its accomplishment would, of course, need new legislation based upon knowledge obtained from very careful scrutiny of the past ten years' experience for the whole country. The successful construction of a separate National Health Insurance society or association of persons not attached to an approved society naturally depends entirely upon the general average health standard of such persons being equivalent to or higher than the standard of that of approved society members. The last valuations of approved societies established that, generally speaking, members of societies had been a good insurance proposition at the contribution rates prevailing over the valuation period.

In the absence of any knowledge of a valuation of the deposit contributors' fund or of the operations on the deposit contributors' accounts as a whole during the past ten years, however, it is extremely difficult for me to present any data which will assist in arriving at a decision whether deposit contributors do in fact represent a good insurable class at present rates. The only information to be gleaned from the report of the Ministry of Health on this point is that as regards England, at the 31st December, 1921, 250,000 personal accounts remained open, that 75,000 applications for transfer to approved societies were received during the year 1921, and that during the same period £35,834 was paid in sickness benefit—only nine payments being in respect of disablement benefit—£16,224 was paid in maternity benefit, £938 was paid upon death, and £765 was paid on emigration; while at the 31st December, 1919, the balance in the fund was £958,733. Unfortunately those meagre facts do not give much help. Other data are required before our discussion thereon can be other than purely academic. But why should deposit contributors as a group be barred from extra benefits and disablement benefit in its entirety, and the more unfortunate of the deposit contributors be cut off from all benefits upon exhaustion of individual credits when the central fund balance exceeds £900,000?

In West Ham during the last five years—viz., January, 1918, to January, 1923, the average number of deposit contributors on the register was 3086; the number of persons who claimed sickness benefit was 696; or only 22 per cent. The number of persons whose claims were fully paid was 462, or 66·4 per cent. of the claimants, and those who suffered loss or diminution of benefits by reason of exhaustion of balance was 234, or 33·6 per cent. of the claimants. (Once 218 persons; twice, 16 persons.) The number of sickness benefit claims certified during the period was 2816. The number of claims paid was 2531, while the number unpaid owing to the balance exhausted was 285. The number of claims for maternity benefit certified during the period was 631, of which 471, or 75 per cent., were paid in full, 29 were paid over three-quarters of the amount, 35 were paid between half and three-quarters of the amount, 39 were paid less than half of the amount, and in 57 cases—less than

10 per cent.—no part of the amount was paid because the balances had been exhausted or for some other reason.

I cannot, of course, claim finality in the conclusion to be deduced from these figures, but I suggest that with the experience of sickness benefit claims of only 22 per cent., the payment of sickness benefit claims in full to the extent of 66½ per cent., and of the payment of maternity benefit claims in full to the extent of 75 per cent. in a great industrial area such as mine, coupled with the enormous balance that appears to be standing in the Central Deposit Contributors' Fund, a prima facie case is presented in favour of the suggestion that deposit contributors as a group form a good insurance proposition.

Assuming, therefore, that deposit contributors as a whole are good insurance subjects from the general average health aspect, I suggest that a National Health Insurance Association of these persons, administered by the present insurance committees jointly, is within the realms of practical politics. The present position of these people represents one of the most glaring injustices of the National Health Insurance Acts. The fact that many of the people concerned may be voluntarily suffering injustice does not, to my mind, relieve the responsible authorities from the obligation to place these and all other insured persons upon an equal footing as regards the benefits, as well as regards the contributions of the Acts. In conclusion, I repeat that every effort should be made to secure early establishment of a system whereby insured persons who do not of their own accord or within a limited time join one or other of the present approved societies, shall be guaranteed benefits of no less value than those guaranteed under the Acts to the members of approved societies.

THE OPENING OF THE MAUDSLEY HOSPITAL.

Sir Arthur Griffith-Boscawen, Minister of Health, formally opened the Maudsley Hospital, Denmark-hill, London, S.E., on Jan. 31st. This is the first hospital provided by a public body in England for the treatment of early and recoverable types of mental disorder. Mr. F. R. Anderton, chairman of the London County Council, was in the chair. Mr. D. Cawdron, chairman of the Mental Hospitals Committee of the L.C.C., gave a short account of the establishment and purposes of the hospital, during which he stated that the Council had between 18,000 and 19,000 mental cases to deal with. The hospital, he said, would admit none but voluntary cases; no certified case would be admitted, and no person would be certified therein. It was considered that this decision would be very useful in persuading patients to seek treatment, especially when the latter realised that they could discharge themselves at 24 hours' notice. It was recognised that certain forms of incipient mental disease would not be represented in the hospital, but it was hoped that legislation would shortly make it possible to deal with those types of disorder without certification. Much would be hoped for from the institution, both in the way of benefit to patients and for the advancement of medical science; its success would be the finest testimonial to the great man to whom it owed its being.

Sir Arthur Griffith-Boscawen emphasised the importance of the occasion, in that it marked the inauguration of a new era in the treatment of mental disease. The new departure would, he hoped, save a great deal of suffering in the future. The community generally, and the London County Council in particular, were greatly indebted to the generosity and foresight of the late Dr. Henry Maudsley. Dr. Maudsley's three main interests, to which he devoted much of his life's work, and for which he made most generous provision, were, first, an attempt to deal at an early stage with certain cases of mental disorder, thereby rendering them curable; second, a keen desire to establish exact research into the causes of mental disorder; and, third, a great anxiety to see the proper clinical instruction of students carried on. It had long been recognised that much could be done by early treatment on a voluntary basis, and while grave difficulties surrounded the subject it was most desirable that attempts should be made on proper lines to deal with that great problem. Here they had the chance. He hoped that in the near future Parliament would find time to deal with the whole question of the early treatment of recoverable mental cases, so that similar experiments might be carried out by other local authorities. When Minister of Agriculture he had always urged that progress must depend on research. A great deal of exact research into mental disorder had already been carried out, and here was an institution in which those more or less sporadic inquiries could be concentrated and focused. Medical students had a great deal to learn, but there was no reason why they should neglect mental disorder, and if the work were carried on in close coöperation with the great teaching hospitals and the University of London he felt sure that knowledge would be gained and the opportunity provided for preventing endless suffering in the future. He was glad that special attention had been paid to the selection of the nursing staff. Many unjust aspersions had been cast of late on the nursing staffs of mental hospitals; he was glad that at that institution the nurses selected had had a general hospital training, which was by far the best training for their special work. The committee appointed by his predecessor at the Ministry of Health to inquire into the administration of mental hospitals in this country had recently issued a report generally disabusing the public mind and repelling criticisms, but pointing out certain directions in which progress might be made. Among those directions were the provision of early treatment, concentration of research, higher qualification of the medical staff, a higher proportion of hospital-qualified nurses, and increased opportunities for consultation. Those were the very objects which this hospital had in view, and they were anticipating what Parliament might do in the directions recommended by the committee. He then expressed his great pleasure in formally declaring the hospital to be open.

A vote of thanks to the Minister of Health was proposed by Mr. W. Sidney, vice-chairman of the Hospital Sub-Committee, and seconded by Captain C. D. Kingston, L.C.C. Replying, Sir Arthur Griffith-Boscawen wished success to the institution, making special mention of the names of Sir Frederick Mott, director of the pathological laboratory, and of Dr. E. Mapother, medical superintendent of the hospital. The Minister and members of the Council then made a tour of the hospital.

BURDETT'S HOSPITALS AND CHARITIES, 1922–23.

THE thirty-third issue of this well-known year-book of philanthropy and hospital annual (London: Scientific Press, Ltd. Pp. 875. 17*s.* 6*d.*) contains the usual concise information regarding hospitals and all other forms of medical, nursing, and convalescent establishments in this country, throughout the Empire, and in the U.S.A. The military and naval section has been enlarged, the new names of Poor-law infirmaries are given, and a list of the local committees set up by the Voluntary Hospital Commission appears for the first time in the pages of the year-book. The statistical information has been brought forward a year, so that the year of statistics given in chapters and tables is now identical with that—i.e., 1921—in the directory section. The tables of income and expenditure of convalescent homes, omitted last year pending a return to more normal conditions in connexion with these institutions, has now been reinstated.

A DIRECTORY OF BRITISH CHEMICAL PRODUCTS.

WE have received from the Association of British Chemical Manufacturers, Incorporated, a copy of the new edition of the official directory of the Association for 1923. The directory contains the names of some 150 chemical manufacturers, with a classified list of their products. A section is devoted to proprietary and trade names. The list of products, which is given in more detail than formerly, is reproduced in French, German, Italian, Spanish, and Portuguese for the convenience of overseas buyers. British Commercial Attachés, Consular officers, and Trade Commissioners, and the various Government purchasing departments should find it a valuable work of reference. The Association is prepared to advise on matters relating to the chemical trade, and welcomes inquiries with regard to any particular product. The price of the directory is 10*s.* 6*d.*; copies may be obtained from the offices of the Association, 166, Piccadilly, London, W. 1.

A USEFUL MAP OF LONDON.

EVERYONE who travels by the London Electric Railways has no doubt found cause for amusement and admiration in Mr. MacDonald Gill's poster, depicting the central area traversed by their lines, and executed somewhat in the manner of the old cartographers who filled the less-known portions of their maps with drawings of savages and dragons, interspersed with such legends as "Here is gold." The map is one of which the metropolitan health authorities should take note, for the cartographic art might be utilised far more than it is in the interests of hygiene. A map of London's hospital and first-aid arrangements on Mr. Gill's lines would meet a real need; lessons on local overcrowding and undue infant mortality could be drawn pictorially, and form a useful item of child welfare propaganda. Directions in which healthy expansion countrywards can still take place might be indicated. The scope for the hygienic reformer seems, in fact, almost limitless. The map is plotted on a scale of six inches to the mile; copies may be obtained (price 5*s.*) from the traffic advertising agent, Electric Railway House, Broadway, Westminster, S.W. 1.

SELECTIVE ACTION OF COAL-TAR DYES ON MICRO-ORGANISMS.

AT the Royal Society of Arts on Jan. 31st, Sir Humphry Rolleston, P.R.C.P., being in the chair, the Mann Lecture was delivered by Mr. T. H. Fairbrother, M.Sc., and Dr. Arnold Renshaw, on the Relation between Chemical Constitution and Antiseptic Action in the Coal-Tar Dyes. After dealing fully with the elemental structure of eight different groups of dyestuffs, the authors asked themselves the question: "Is there any selective action possible in regard to the action of dyes upon the minute forms of life, bacterial and protozoal?"

The Facts of Selection.

The answer to this question, they say, is that considering the whole range of dyes, some dyes possess destructive action upon bacteria and upon protozoa, while others in dilutions of 1/200, 1/2000, or 1/20,000 do not, so that speaking generally there are some dyes which exert a more selective action than others. When we consider the dyes possessing this destructive action they fall into the following three groups:—

1. Those which act upon both bacteria and protozoa.

2. Those which act upon some bacteria more than upon others.

3. Those which act in great dilution upon protozoa and in much less dilution upon bacteria.

Thus auramine and crystal violet act upon both bacteria and upon protozoa, and the oxazine dyes, such as Nile blue, Meldola's blue, act much more intensely upon protozoa than upon bacteria. Again, there are other dyes which act more powerfully upon the Gram-positive organisms like staphylococci, *B. diphtheriæ*, and even upon anthrax spores than upon the Gram-negative organisms, such as *B. coli* and *B. typhosus*. Even amongst the Gram-negative group—*B. coli*, *B. lactis*, *B. paratyphosus* A and B, *B. enteritidis* (Gaertner), *B. dysenteriæ* (Shiga), and *B. dysenteriæ* (Flexner)—there is a certain amount of gradation. Thus we have often noticed that Shiga and Flexner are killed more easily than *B. coli* and *B. lactis*, whereas *B. typhosus* occupies an intermediate position. For this reason *B. typhosus* cannot be regarded as a suitable organism for the routine testing of disinfectants. A curious fact emerges in regard to *B. phlœi*—the Timothy grass bacillus, an acid-fast bacillus, resembling in some respects the tubercle bacillus. Presumably like the tubercle bacillus it has a lipoid envelope and so it ought to resist fairly well the action of many of the dyes, yet in our results it was often killed.

The Reasons for Selection.

Are there any reasons, the authors ask, to account for this apparent difference or selective action of dyes upon bacteria and upon protozoa. Some years ago one of us found that a culture of a unicellular plant—the protococcus—could be purified and separated from associated bacteria by immersing the mixed culture in a certain dye solution over a period of days, after which on subculturing into a suitable nutrient fluid a pure culture of the protococcus resulted. Previously all other methods had failed to yield a pure culture of the protococcus. In this experiment the protococcus had resisted the action of the dye which was present in sufficient strength to kill the bacteria. Here the stout cellulose wall of the protococcus had prevented the penetration of the dye to the more vital part of the cell, which still showed unchanged chlorophyll, albeit the cell had entered into a spore stage during the time of immersion in the dye.

Resistance to penetration of the dye is therefore a factor which sometimes helps to explain poor antiseptic action, and it may explain some of those cases in which naked protozoa are killed more readily than bacteria possessing a cell wall. It is not, however, the only factor, for in some cases protozoa may be immersed in a dye and actual vital staining of the cell may occur without death resulting, as in the case of methylene-blue. It is probable, therefore, that the dye has some action either upon the medium in which the bacteria or protozoa are present; or, and more likely, that the dye has a chemical or physical action, or both, upon the organism. In view of the staining which occurs, most often of the nucleus of a protozoon, and sometimes of the protoplasm, it is probable than an actual chemical action takes place leading to a destruction or alteration of the chemical components of the living cell.

Selection not Confined to Dyes.

One fact, however, emerges fairly clearly, and that is that selective action in the dyes is not confined so much to individuals as to broad classes of similar infective agents, and that among these classes selective action of a more restricted type is possible within narrow limits. This fact is not confined to dyes. In the case of salvarsan the drug may act not only upon the *Spirochæta pallida* of syphilis, but upon other spirochætes and even upon spirilla, as shown by its surprising effect upon Vincent's angina. A similar fact apparently holds good in regard to Bayer 205 since this can act not only upon the trypanosome of sleeping sickness, *T. gambiense*, but upon *T. equiperdum* (rats), *T. brucei*, *T. equinum*, and *T. rhodesiense*.

Test Objects.

In our earlier work we used paramœcia largely for purposes of convenience, and ease of observation, and to enable us to run quickly through the list of dyes with the object of detecting those having any protozoal action at all. Having done this we ascertained the effect upon other protozoa—e.g., amœba, and upon trypanosomes. We tried the effect of two of our most active dyes, auramine and Nile blue, separately and in varying dilutions, upon trypanosomes freshly obtained by bleeding a mouse infected with *T. venezuelense*, and found that within 15 minutes a dilution of 1/20,000 of auramine, or 1/20,000 of Nile blue A was sufficient to cause death to all the trypanosomes in the film; whereas control films kept under the same conditions showed great activity at the expiration of even 30 minutes. These results coincided with the dilutions and times in our paramœcium work. Somewhat similar results had formerly been obtained with another flagellate, euglena. Accordingly, we believe that the results obtained with paramœcia can be translated into terms of trypanosomes, and we have no doubt but that dyes which will kill the former will kill the latter in the same dilutions and within the same time. A recognition of this fact should expedite very considerably future research on trypanosomiasis.

Results.

As it is, we have been led by means of our work on paramœcia to the discovery of a dye which we know will kill trypanosomes within 15 minutes in a dilution of 1/20,000. The comparison of this dye with the results quoted by Wenyon in the case of Bayer 205 is proceeding. The comparison between paramœcia and higher forms such as the filariæ is not quite so close, but even here we were able to obtain some resemblance. We have examined the action of the dye on the minute worms or filariæ present in a man suffering from this infection, and we found that auramine again killed the filariæ in five minutes in a dilution of 1/4000 and in 20 minutes in a dilution of 1/8000 when mixed with the patient's blood.

Thus the oxazine group of dyes shows selective action between bacteria and protozoa and to a lesser extent amongst bacteria themselves, killing off paramœcia in high dilution, Gram-positive organisms in lower dilution, and, in dilutions used, not killing off Gram-negative bacteria at all.

"ROUND THE FOUNTAIN."

EVERY teaching hospital has its particular quips and quirks which serve to relieve the strain and monotony of the medical student's daily round. While most of these may have no permanent value, there are literary gems which should not be lost. Mr. B. T. Lang was responsible for the first collection of verses and sketches appearing from time to time in the *St. Bartholomew's Hospital Journal* or forming part of various private collections. This was printed in 1909 under the title of "Round the Fountain," the editor then acknowledging his indebtedness to F. A. Bainbridge, W. M. Borcherds, W. Langdon Brown, R. C. Elmslie, A. H. Hogarth, T. J. Horder, N. G. Horner, H. B. Meakin, J. A. Nixon, K. Pretty, R. B. Price, H. Pritchard, and E. Talbot, his predecessors in the editorial chair. An undue proportion of these are no longer with us, and the remainder have attained distinction in various walks of medicine. This first edition was exhausted within six months, the considerable profits being handed to the Nurses' Home Rebuilding Fund. A new and enlarged edition appeared in 1912, and Mr. H. L. Sackett has just brought out a third edition containing 40 additional pages. Much sound pathology can be read between the lines of the "Disrespectful Ditties" regarding "Dr. Richard Bright of Guy's," "Poor Pa Parkinson, rolling cigarettes," and others. A note on Speeding-up the Out-patient Department can hardly fail to cheer, as also a Suggestion How to Brighten the Clinical Note. The book costs 2*s.* 6*d.*, postage 2½*d.* extra, and is to be obtained from the Journal Office at St. Bartholomew's Hospital, London, E.C. 1.

Hunterian Oration

ON

JOHN HUNTER

(1728–1793),

HIS AFFAIRS, HABITS, AND OPINIONS.

Delivered at the Royal College of Surgeons of England on Feb. 14th, 1923,

By Sir JOHN BLAND-SUTTON, F.R.C.S. Eng.,
CONSULTING SURGEON TO THE MIDDLESEX HOSPITAL.

My knowledge of John Hunter began in a curious way. In my ninth year I was taken to see his famous house at Earl's Court, and shown the den in the garden where he kept wild beasts in order to study them. Being fond of animals, this made a deep impression on my mind. In the simple religious exercises of my childhood, the story of Adam and Eve, the first keepers of a zoological garden, and the famous exploit of Noah, collector and preserver of wild animals, had great charm for me. Some years later the visit came vividly to my mind on finding a dilapidated copy of Ottley's Life of Hunter, which I read eagerly. Ever since I have been deeply interested in all that relates to this extraordinary man, and the preparation of this oration has been a delightful and engrossing occupation.

Long Calderwood (1728–1748).

John Hunter was born at the farmhouse, Long Calderwood, near Glasgow. The house bears a tablet to the effect that he was born Feb. 13th, 1728. In his life-time the birthday was kept Feb. 14th, and this College drinks to his memory in "solemn silence" on the 14th. Like myself, he was probably born so late at night that in the hurry-scurry the midwife failed to notice whether he appeared just before or shortly after the clock struck 12. John, or Jockie, as he was called at home, the youngest of a family of 10, petted by his mother (his father died in 1741, aged 78), disliked school and hated books. He preferred to lead an out-of-door life, looking after nests, insects, and animals, whilst his brothers got the same education as country gentlemen. At the age of 17 he spent some months with a brother-in-law, a timber merchant and carpenter in Glasgow, and we can well believe he tried his hand with tools; his mother noticed that the "lad showed neatness of hands and quickness of perception in anything that regarded mechanism." What inquisitive boy has not meddled with awls and gimlets, mallets and chisels, hammers and nails, saws and planes? Sharp boys can learn much that is useful in workshops, and a training in joinery teaches neatness and precision. Looking back it is instructive to consider how the farm life fitted John Hunter for his subsequent career. The practical surgeon is a craftsman; Greek and Latin are useful to him for polish, but think of the natural knowledge a smart boy can collect on a farm about the sowing, sprouting, and ripening of crops, the breeding of animals, gelding of colts, spaying of pigs, caponising of cocks, fattening and slaughtering of animals for food, farriery—shoeing and doctoring of horses—observing the wild life in ponds and ditches, fields and hedgerows, trees and heather. In the village he can watch the wheelwright, smith, tinker, glazier, cobbler, and cooper, all experts with simple tools. *Practical knowledge of this kind was useful in that state of life unto which William Hunter called his youngest brother.*

Human Anatomy (1748–1760).

At the age of 20 John Hunter came to London with the object of assisting his brother William, who had a school of anatomy at the back of his house in Covent-garden. John showed unusual skill in dissecting, worked hard, liked the companionship of men of his own age, and was fond of the theatre. There can be no doubt that he was an example of the medical student skilfully described by Dickens in "Pickwick Papers," 1836, and Albert Smith in *Punch*, 1841. Human anatomy appealed to this uncouth Scot, and William Hunter, a cultured man, moulded John's character, and "bred him to anatomy" in its widest significance with astonishing results. In the summer of 1754 Hunter was busy studying the routes by which the branches of the fifth nerve leave the skull. He unravelled the branches of the olfactory nerve, traced the course of the naso-palatine nerve, and the rambling nerve known as the nasal branch of the ophthalmic division of the fifth; a specimen (Fig. 1) he dissected to show these nerves exists in the Museum in excellent condition.

Hunter's attention was arrested by the uniformity in the course and distribution of nerves in comparison with the vagary of blood-vessels. Even now few grasp the problem presented by the branches of the olfactory nerve, which run down the anterior border of the nasal septum. In 1811 Jacobson, a surgeon in the Danish Army, discovered a curious organ lodged in a scroll of cartilage situated on the anterior part of the base of the nasal septum (Fig. 2).

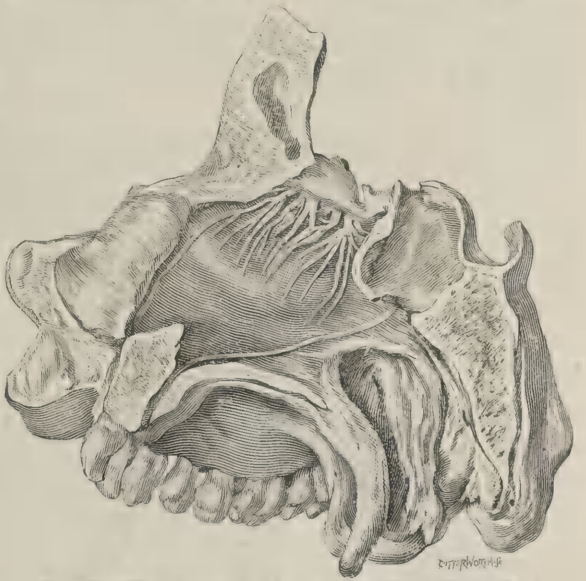

Fig. 1.—The nerves on the nasal septum (Hunterian).

Jacobson's organ—a vestige in man, apes, and whales—is well developed in many mammals. Little is known of its function, but the specialised cells lining its cavity receive the olfactory twigs detected by Hunter. Jacobson's organ is well developed in mammals with long snouts, especially insectivora that find food at dusk; rodents whose young are born blind and live in deep burrows, and kangaroos whose young must find their way into, and pass many weeks snugly ensconced in the mother's warm pouch. The prime service of olfaction is the quest for food. The sense of smell is of first-rate importance to mammals born blind—*it enables them to find the teats of the mother.* The vomero-nasal organ is subsidiary to the olfactory nerve.

The morphology of the canals and foramina by which the cranial nerves leave the skull has always fascinated me, and many delightful hours of my life have been spent unravelling the secrets connected with their methods of exit, re-entrance, and final escape from the skull. The study interested Hunter apart from its morphological aspect. In his days vestiges were merely anatomical curiosities. How much greater the interest for us studying them in the light of man's evolution. For Hunter, morphology was a gleam in the intellectual sky. We revel in the sunshine. Morphology has become the soul of anatomy.

Many regard the dissection of the human body as a repulsive exercise. Teachers of anatomy know well that many begin to dissect with disgust and overcome the distaste; others continue the study because it fits a man for the medical profession. Some who have found difficulty in retaining or appreciating the facts of anatomy have shone in other professions. On the other hand, men unable to grasp mathematics or the principles of physics have become proficient anatomists. In a few instances men working at a humdrum calling turned to anatomy more or less accidentally and pursued it with zeal. It is easy to understand that the uncouth, unschooled, apparently idle Jockie Hunter when introduced to the dissecting-room became deeply interested in the structure of the human body and found it an absorbing study. *Verily the gunpowder of genius is stored in many brains, but—it needs a match.*

BELLEISLE (1760–1762) AND MARINE ZOOLOGY.

Hunter, during the first period of his life in London (1748–1760), acquired a practical knowledge of human anatomy, but this was mainly a study for the winter months. During the summer he studied surgery, following Cheselden for a season, also Pott, but St. George's Hospital offered better opportunities, and he joined as surgeon's pupil, and later had the good fortune to serve as house surgeon for two years, an invaluable experience. Whilst engaged in the routine of dissecting and teaching he developed a taste for comparative anatomy which became an absorbing passion, enhanced by a change of locality. In the spring of 1759 he had some lung trouble which made it necessary for him to seek change of climate. In 1760 a force was sent from England to take Belleisle, an island near the mouth of the Loire. Hunter applied for an appointment with the expedition and served as staff-surgeon. This gave him a chance of obtaining practical knowledge of gunshot wounds.

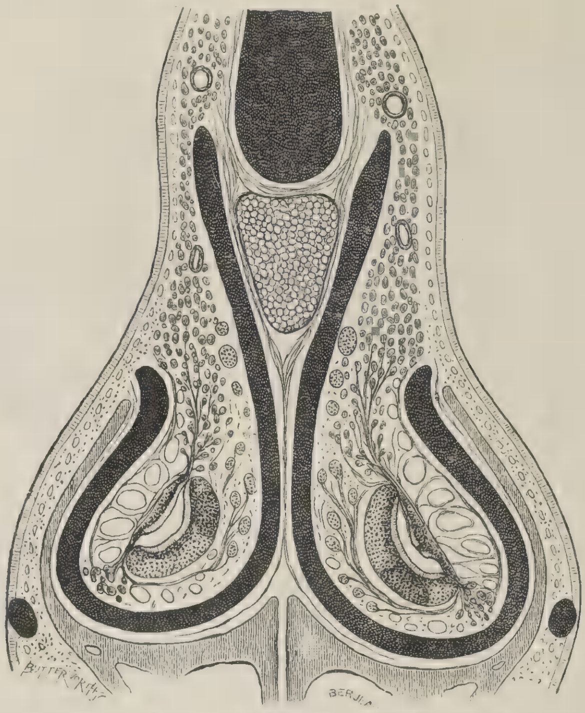

FIG. 2.—Section of a rabbit's nose exposing Jacobson's organ (Klein).

Belleisle, well named, is a pretty island now almost tree-less. It is a plateau of 33 square miles, about 130 feet above sea-level; here and there slopes give access to beautiful tracts of white sand. The coast has many grottoes. The most remarkable is La Grotte de l'Apothicairerie, a sanctuary for sea-birds, and their nests in rows on ledges of the rock are supposed to resemble bottles on the shelves of a pharmacy. I spent a week in this island and realised what a change it proved for a man from London, ardently pursuing comparative anatomy. A country new to him in flora and fauna. He took advantage of it by observing, collecting, dissecting, experimenting, and preparing and preserving specimens. Hunter had no knowledge of marine zoology until he landed on this charming island, which afforded him access to barnacles, sea-anemones, sea-stars, sea-nettles, sea-cucumbers, sea-squirts, sea-urchins, squid, huge spider crabs, tunny-fish, and conger eels.

While studying and dissecting these animals the idea came into his mind that living creatures could be arranged in a physiological series, but he was puzzled to ascertain the use of strange organs he met with in marine invertebrates. Like Cuvier, he had to rely on naked-eye dissection, but dissection, however skilful, does not enable anatomists to determine the minute structure of soft organs which is the key to function. These difficulties are shown in Hunter's studies of the reproductive organs of eels. He truly observes "the production of animals out of themselves excites wonder and curiosity." The precise manner in which it is carried out has required centuries of observation for its demonstration. The eggs of flies, butterflies, fishes, frogs, turtles, crocodiles, snakes, and birds appeal to the simplest mind. It was difficult to prove that mammals came from eggs, for their small eggs require a microscope to make them visible. This is true of mice and men.

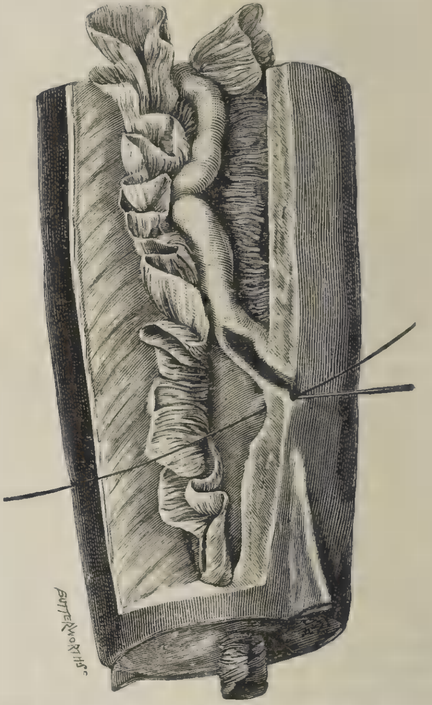

FIG. 3.—Segment of an eel showing the ovary. The bristles mark the end of the rectum and the abdominal pore (Hunterian).

In London he got eels every month of the year from a fishmonger and examined the parts he expected to be the ovary with a magnifier but without result. When he was in Belleisle in the summer of 1761, there was a vast number of conger eels in the sea around the island; he dissected many and satisfied himself that the ruffle-like organs he regarded as ovaries in the common eel were ovaries (Fig. 3), but he did not solve the mystery of the propagation of eels. In 1896 Grassi discovered that eels needed salt water for the development of their reproductive organs and the deep sea is their spawning place. In autumn they migrate to the sea and the dull yellow of their skin changes to silvery glitter; the eyes enlarge, the pectoral fins become black and change in shape (Fig. 4), and the ova ripen.

Mature eels cease to feed and after spawning die. Recently hatched eels, called *Leptocephali* on account of the small size of their heads, are transparent and free from colour, except the eyes, which shine through the water like black beads. When about 7 cm. long *Leptocephali* cease to feed and change into elvers, which in spring find their way up the rivers in enormous numbers. The migrations of eel-fry are astounding in extent and duration. In some instances larvæ will traverse a quarter of the circumference of the globe to complete their life-history (Schmidt). Elvers in fresh water transform into eels, and in their turn descend the rivers, seek the depths of the sea, where decked in glorious sheen they spawn and die.

Although Hunter did not get on well with his senior colleagues at Belleisle, he was comfortable on his pay, and enjoyed the opportunities for studying natural history, but in 1762 a British expedition to Portugal was the topic of conversation; he was keen to go, and his brother William helped him with the authorities in London to do so.

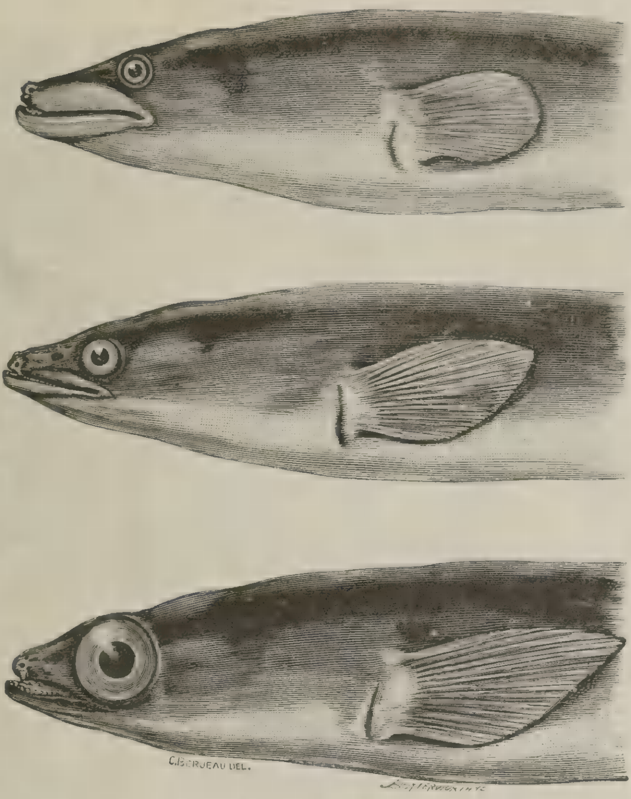

FIG. 4.—Drawings showing the change from the yellow eel with thick lips, small eyes, and compact fin, into the large-eyed silvery eel, which migrates to the ocean, where it reaches maturity, spawns and dies. (From models in the Natural History Museum.)

PORTUGAL AND GEOLOGY (1762–1763).

One of the last episodes of the Seven Years' War was an attempt on the part of France and Spain to invade Portugal. The French and Spanish forces were collected at Ciudad Rodrigo with the object of advancing on Lisbon along the Tagus valley. England decided to support Portugal and an expeditionary force of 7000 men was sent to Lisbon. The British and Portuguese troops, under the command of Count Schambourg-Lippe, an able officer trained in the school of Frederick the Great, assembled on the banks of the Tagus near the Spanish border. The outstanding feature of this almost forgotten campaign was the use, for the first time, of light cavalry which General John Burgoyne was instrumental in introducing into the British army. Under Burgoyne the cavalry rendered distinguished service at Valencia d'Alcantara and in some sharp fighting at Villa Velha. The campaign was concluded by the Peace of Paris, 1763. Mr. Robert Boyne Home was the surgeon attached to the regiment of light horse. John Hunter, transferred from Belleisle to Portugal, was in charge of a hospital. Hunter landed at Lisbon, July, 1762, and in November of the same year he was at Portalegre, near the Spanish frontier 140 miles from Lisbon. General headquarters was at Estremoz, 30 miles south of Portalegre, and on the direct road to Lisbon. Little is known of his doings in Portugal, and it has been supposed he made additional observations on gunshot wounds; for this there was not much opportunity, but with a force of 7000 men there would be accidents and sickness incidental to a campaign in a foreign country.

It is certain that in Portugal Hunter made observations on natural history and collected specimens, some of which are preserved in the Museum, but the most important gain was an inspiration to study geology. The hill on which Portalegre is built stands on a remarkable plateau called Alemtejo (spelt Alentejo in 1763). In an extraordinary tract published about 50 years after Hunter's death, under the title "Observations and Reflexions on Geology," he refers to the extensive plateau called Alentejo, which shows evident signs of its surface being covered by the sea, and refers to the enormous heaps of granite so frequent on the plain. The tract not only contains remarkable observations on geology, but some ideas on the distributions of animals in relation to the antiquity of the world inconsistent with the creation as described in Genesis. He abstained from publishing it on the advice of friends. Recently I visited Portalegre, the Alemtejo, and the surrounding country, and satisfied myself that Hunter while living on the plain had excellent inducements to study botany as well as geology, for he was among a sub-tropical flora, and at Lisbon he had opportunities of collecting specimens and adding to the knowledge of marine zoology he had acquired at Belleisle.

Hunter's domestic life was influenced in an important manner by the affairs of Portugal, for Home, surgeon to Burgoyne's regiment of light horse, became his friend. Hunter on his return to England got engaged to Home's daughter, Anne. It was a long engagement, for they were not married till 1771. Mrs. Hunter's younger brother Everard, became Hunter's house-pupil, then his assistant, and finally executor.

Sir Everard Home and Matthew Baillie founded the Hunterian Oration in 1813 and Everard Home was the first orator, 1814.

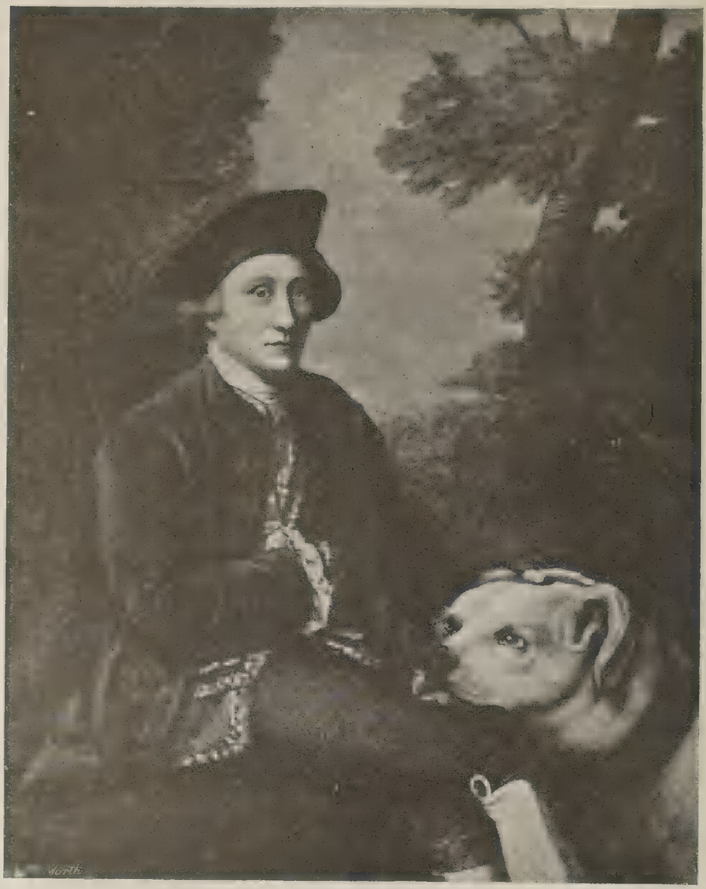
EARL'S COURT.

On the conclusion of peace Hunter returned to London a staff-surgeon and deputy-purveyor on half pay. He took a house in Golden-square and started to practise. His half pay, probably half a guinea a day, helped to pay the rent. He opened a room for dissecting, made teaching preparations, and while waiting for patients, like many of us, taught human anatomy for capital and comparative anatomy for interest. The classes were neither large nor lucrative, for he was not a good lecturer. In 1765 he bought the lease of three pieces of land at Earl's Court, built a house, established a small menagerie, and made observations and experiments:

> On gizzards of gulls, hawks and owls,
> The heat of lizards, spurs of fowls;
> Bones of pigs, air-sacs of eagles,
> Moaning dingos, barking beagles;
> Sleek opossums, prickly hedgehogs,
> Buffaloes, dormice, wolves and dogs.

Leopards and jackals lived in the den, buffaloes, stallions, sheep, goats, and rams occupied the stables. A mulberry tree furnished leaves for the silkworms and St. John's wort supplied pollen for bees. There was a pond for the ducks and geese which laid eggs for the table and for embryological studies. He made observation hives for the bees, discovered that their wax is a secretion, and left some excellent notes on the relation of vegetables to animal fat. With the aid of Ramsden's delicate thermometers he discovered the significance of the terms hot-blooded and cold-blooded animals. He would have been astonished to learn that muscular action is the main source of animal heat! Hunter failed to grasp the importance of measuring the temperature of the body for clinical purposes. Indeed, its value was not appreciated until the middle of the nineteenth century.

Earl's Court remained a bachelor's residence for seven years. In 1771 John Hunter, aged 43, married Anne Home, aged 29, a charming, amiable, and accomplished spinster, who, in due course, added to the physiologist's paradise the most delightful of all objects of natural history — children. Mrs. Hunter had a brother, Robert Home, an artist, who painted a portrait of Hunter which eventually came into the possession of the Royal Society (Fig. 5). In 1787 Hunter read a paper before that society on some observations "tending to show that the wolf, jackal, and dog are all of the same species." The odd dog in the picture is supposed to be the offspring of a half-bred wolf-bitch and an English mastiff. The dog died in 1782. The portrait represents Hunter about the age of 45. He describes himself at this period in a letter to James Baillie, his brother-in-law, as "one of the happyst men living" (1775), in spite of the fact that he had to raise money on the Earl's Court property, a fact concerning which Dr. G. C. Peachey has found unimpeachable documentary evidence. Hunter was a resident at Earl's Court 30 years. In 1877 the Royal College of Surgeons, and a few friends, placed a window to his memory in St. Mary Abbott's Church, Kensington. One of the principal lights represents St. Paul on the island of Melita casting a viper off his hand.



JOHN HUNTER.

FIG. 5.—The picture is by Robert Home. The odd dog is supposed to be the offspring of a half-bred wolf-bitch and a mastiff.

THE MUSEUM.

Nothing is known of the time Hunter began to collect specimens with the definite object of establishing a comprehensive museum of comparative anatomy. The museum owes its origin to the peculiar conditions under which medical education was carried on in London in the eighteenth century. Schools of anatomy were private ventures. It was necessary for the surgeon who owned and managed the school to illustrate his lectures with skilfully prepared specimens. Such preparations are more useful than diagrams, wax models, or drawings on blackboards, even when made with skill and coloured chalk. Hunter made many preparations for his brother, and some exist in the Hunterian Museum at Glasgow, but when he returned to London in 1763 he brought with him specimens of natural history from Belleisle and Portugal, and these formed the nucleus of the collection for illustrating comparative anatomy. It is a fair inference that the specimens were collected to subserve teaching purposes directly connected with his lectures, but it grew and widened until it became a museum that could be regarded as a discourse on the human body in relation to the animal kingdom. Gradually its founder's ideas expanded, and he conceived that it should be an ample illustration of life exhibited in the vast chain of organised beings, living and extinct, by a display of the various structures in which the functions of life are carried on.

In 1783 the lease of the house, 42, Jermyn-street, which he had acquired from his brother William, expired. He then took premises in Leicester-square and built his famous museum. Sir Joshua Reynolds lived in the square, and the two men subsequently helped each other to what artists jokingly call immortality—one as subject, the other as painter. The famous picture is the most cherished possession of our College. When Baron Grant furbished up Leicester-square and laid out the garden in 1874, a colossal bust of Hunter was placed in one corner and a bust of Reynolds in another.

Hunter's example in collecting specimens was contagious. Blizzard, Astley Cooper, Heaviside, and other surgeons formed collections, now dispersed. The care entailed in the maintenance and supervision of such museums is very great. Hunter's museum nearly perished. His executors, Matthew Baillie and Everard Home, with sound judgment, retained the services of William Clift, who preserved the specimens from decay by the judicious use of two gallons of spirit occasionally. He had no books, so he read and made extracts from Hunter's manuscripts. The transcripts were made from some of the notes afterwards destroyed by Everard Home. They were published by Owen under the title "Essays and Observations," in 1861. For seven years Clift received 7*s*. weekly and meekly as wages. In return for these services he became the first conservator when the Government bought the collection and intrusted it to the College of Surgeons in 1800. Clift was conservator till 1842. The museum contains in orderly array, big and little, of every living thing Hunter could secure. Shrimps and sharks, humming-birds and ostriches, shrews and whales. Of the human kind, dwarfs and giants. Animals now living on the earth were not enough, he must have fossil forms. The fame of Hunter was such that new or rare animals were brought to London for his opinion. When John White returned to England (1790) from New South Wales "the nondescript animals of that settlement"—kangaroo, potoroo, tapua roo, and the like were handed to Hunter for investigation. The museum is now so rich in specimens illustrating the anatomy of vertebrates, living or extinct, normal and abnormal, that no one who is prudent ventures to publish anything he thinks new without examining the correlated specimens in the museum. It abounds in surprises, and is in a sense an anatomical Valhalla.

PATHOLOGY.

Specimens illustrating "diseased action" were preserved in the museum. Pathology is a department of biology. Hunter's ideas of many pathological processes were crude; without the aid of a compound microscope, section-cutting and staining methods, his knowledge of tumours was not above that of the farrier. Shepherds talk of corns, warts, blains, wens, and blemishes. The slaughter-house supplied him with melanotic tumours from oxen, and from the knacker's yard he got similar things from horses. Graveyards yielded calcified fibroids and tumours of bones. In Hunter's day, and for many years afterwards, pathological specimens were mainly spoils from the dead-house; to-day they are prizes from the operation theatre.

The history of surgical progress during the last 50 years can be traced in the museum catalogue. The hall in the museum that enshrines Hunter's statue is a Temple of Pathology, admirably arranged and catalogued by Shattock. It should stimulate surgeons to study the *science as well as practise the art of surgery.*

EMBRYOLOGY.

Hunter took keen interest in monsters, not from curiosity but as part of a great scheme showing the phases of life. The collection of malformations in the museum is the finest and most comprehensive in the world. He was aware of the importance of a knowledge of the developmental stages of animals, and applied himself to study the chick. He studied the goose because its chick is bigger than that of the fowl. He tried the swan but could not get sufficient eggs. He tried to obtain ostrich eggs but only got two in 30 years, and made nothing out of them. The flock of geese for embryologic work was kept at Earl's Court for 30 years. Although he obtained much first-hand knowledge from this work and some excellent drawings, he discovered little of importance, but left among his notes, awkwardly expressed, for masters of science are rarely masters of style—*Embryology indicates the steps by which higher forms in a group of animals have been evolved from a lower*

Hunter clearly recognised the importance of studying the developmental stages of animals, and 30 years after his death von Baer discovered the human ovum and realised that embryology is the key to the knowledge of the human body.

Hunter collected books but read little. Probably he never read the "System of Philosophy" written by Lucretius, although both men reasoned on inexplicable things.

> *Lucretius.*—Before the horns of a calf appear and sprout he butts when angry and pushes passionately. But the cubs of panthers, and lion's whelps, already fight with claws and feet, and biting, when their teeth and claws are scarcely yet formed.
>
> *Hunter.*—A young duckling runs into the water the moment it sees it.
>
> A hen with ducklings seeing them run into the water is unhappy.
>
> A duck with chickens tries to induce them to enter the water—they run about the bank.

In relation to these paragraphs it may be stated that microscopes and serial sections, aided by the most exquisite stains, throw no light on instinct. Though dogs and pigs do not interbreed, the maternal instinct may be so strong in a bitch that she will suckle a sow's orphans (Fig. 6). *Pity is not an exclusive attribute of gods and men.*

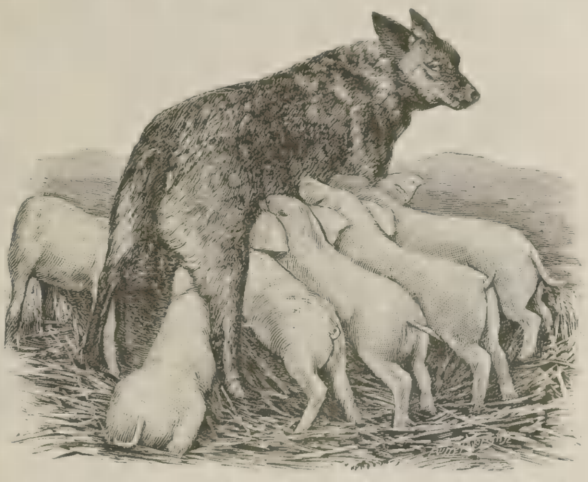


FIG. 6.—Alsatian wolf-hound bitch, whose puppies had died, suckled six little pigs. (*Veterinary Journal*, 1920.)

FEATHER-THICKETS.

In March, 1778, Hunter made this request of his old pupil and friend, Jenner:—

> When you have a blackbird's nest—viz., one with four young ones—take one and put it boldly into spirit by the head, extending the wings and legs. Observe when the feathers begin to sprout, then take another, and serve it in the same way ; then take another and fourth, so as to get a series of the growth of feathers ; but the last or fourth, must not be so old as the feathers to cover other parts where feathers do not grow. This you will understand better when you come to make the trial.

Jenner carried out these instructions admirably (Figs. 7 and 8). About 40 years after Hunter's death Owen found among the MS., transcribed by the faithful Clift, some notes on the situation of feathers:—

> Although the feathers of birds appear to be an entire and uniform covering they do not arise equally from every part of the body, but only from such parts of the skin as are least likely to be affected by the motion of the contiguous parts, such as the motion of the limbs. The feathers arise pretty equally on the head where there is no motion; and along the back; on the wings between joint and joint, as also on the thighs and legs, the whole making the bird a partial coat of mail. As they do not arise from every part of the skin equally, they must be proportionally thick set where they do arise. The places of origin of feathers are very observable in a bird that has been plucked; but still more so in young birds just feathering, more especially of such as have little down, and of which the clumps of feathers, from their colour as in the young blackbird, present a great contrast with the skin. In the interstices of the clumps of feathers there are others disposed irregularly, but so sparingly as not to interfere with the motion of the part.

Hunter named each feather-thicket according to its situation. In 1833 Nitzsch, unaware of Hunter's observation, published "Pterylographia Avium," a study of the distribution of feathers. He called the thickets, *Pterylæ*—feather-forests, and the featherless spaces *Apteria*.

Pterylosis.—The arrangement of feather-tracts is now used by ornithologists as an aid in the classification of birds. Oken cast ridicule upon it; he could not refrain from laughter when he looked at the plates in Nitzsch's book, since they reminded him of the plucked fowls in a poulterer's shop! We must admit that the idea is comic. Newton referring to this joke, adds: "It might as well be urged as an objection to the plates in many anatomical books that they call to mind a butcher's shop!" Hunter had his jibe at the systematists, for, in his opinion, natural historians are more pleased if they can class an animal, than they would be if they could find any use such an animal would be to society.

The value of the feather-distribution (pterylosis) in classification depends on the fact that feather-tracts, like beaks and feet, are modified by the habits of the bird. These callow blackbirds are as instructive as a parable. They prove Hunter's skill in selecting and preparing specimens for museum. The contrast in colour—black and white—is excellent, and the skill shown in mounting them undeniable. They were prepared in 1778 and remained in obscurity until Owen found them 40 years after Hunter's death.

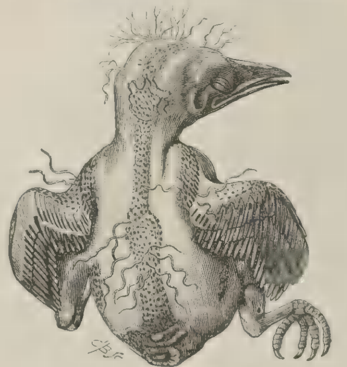

Fig. 7.—Callow Blackbird (Owen).

Hunter had a great power of observation, but lacked the gift of exposition. His discovery was like a lighted candle under a bushel. Half a century later Nitzsch detected the value of pterylosis and urged its importance in classification in spite of ridicule. It is one thing to discover a new fact, but it is another to make contemporaries accept it, or appreciate its value.

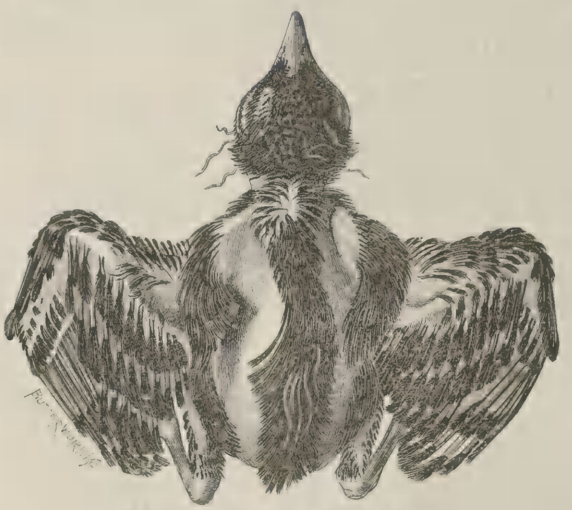

Fig 8.—Nestling Blackbird (Owen).

The Horse.

Hunter studied the horse carefully as an anatomist, and as a surgeon. It was natural that he should study an animal that can walk quickly, amble easily, trot gracefully, or gallop with exceeding swiftness on limbs, each of which ends in a modified toe or finger, and in spite of so many anomalies, be useful to man. He was thoroughly familiar with equine anatomy, the teeth especially, and left a careful description of the curious guttural pouches, connected with the pharyngeal orifices of the Eustachian tubes, which are often a source of inconvenience to horses; and he discovered the curious conjugal ligament which connects the heads of the ribs on opposite sides of the spine. This ligament, well developed also in the seal (Fig. 9), is homologous with the transverse ligament that keeps the odontoid process in position, and which excites curiosity in every human anatomist.

Scattered among his "Observations" there are many references to morbid changes in horses and cattle, and in the museum there are specimens illustrating tumour diseases of horses, oxen, sheep, and pigs.

Hunter helped to found the Royal Veterinary College, 1791; he was a vice-president, and with Cline, served on a committee that approved of the appointment of Vian St. Bel as the first professor of the College. Among the first operations performed by St. Bel was one for the removal of "two accessory feet which grew from the fetlocks of the two forelegs." Hunter assisted and gave him some useful and friendly hints in the course of the operation which was followed by good consequences. St. Bel died in 1793, probably from glanders. His early and unexpected death led to some difficulty, and Hunter, in order to help in the emergency, arranged for the students to have admission to the lectures of the leading teachers in the hospital. The names mentioned in this connexion were Dr. Fordyce, Dr. Baillie, Cruickshanks, and Everard Home. The directors of the College sent Hunter a letter of thanks for his help, which he acknowledged in a letter from Leicester-square, Oct. 2nd, 1793, exactly two weeks before he died. This letter long remained a treasured possession of that College, but it has been lost.

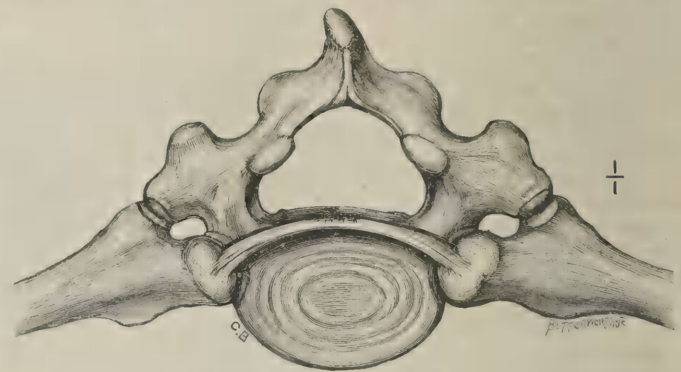

Fig. 9.—Conjugal ligament of the seal.

Hunter's coach was drawn by a pair of bay stone horses. Jesse Foot, his detractor, saw these horses in Piccadilly returning from Hunter's funeral at St. Martin's Church; the circumstance recalled to his mind Virgil's account of the war-horse Æthon, in the funeral procession of Young Pallas, shedding tears!

Whales.

Whales are the biggest animals that exist or have existed on the earth and their skeletons are the most impressive things in the museum. Hunter recognised that whales are land mammals modified to live in the water. He dissected them when he got the opportunity and discovered their semicircular canals. The organ of hearing in these huge mammals is modified in a remarkable manner. The pinna is absent; the meatus is narrow and, in some species, nearly obliterated. The tympanic is a shell of bone; the ossicles—malleus, incus, and stapes—are present. The tympanics are so loosely attached to the skull that when the bodies of whales decompose these bones fall away. In the Central Pacific, detached tympanics, petrosals, and shark's teeth litter the floor of the ocean. Hunter studied the semicircular canals of fishes before he went to Belleisle, and it is reasonable to believe that the structure of the internal ear interested him for 30 years.

Lillie, in 1910 and 1915, made some dissections of the internal ear of whales and explains the vestigeal character of the external auditory meatus by suggesting that whales hear through their nasal passage which opens on the top of their heads. The nostrils collect the sound waves to be conducted through the blow-holes to the huge guttural pouches and the Eustachian tubes, thence to the tympanic bullæ which act as sounding boxes and transmit the sound waves to the chain of ossicles. The shell-like tympanic probably intensifies the sound waves in the water. There is no doubt that whales rely on the sense of hearing and appreciate the pulsations caused by waves striking rocks or the approach of an enemy. These shell-shaped bones are often kept as curiosities. Here is one (Fig. 10) used as a paper-weight by a lady of fashion, yet it collected sound waves that enabled a mighty whale to move through unfathomable waters with the same certainty that the compass enables mariners to guide ships across the trackless ocean.

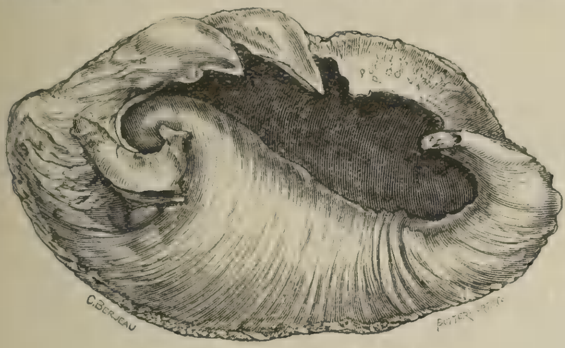

FIG. 10.—Tympanic of a whale.

Intrepid whalemen who have watched whales in the solitary ocean regard them as timid and inoffensive, with large brown eyes and affectionate in disposition to their young. This character does not apply to the toothed whale. The "killer" whale has a large dorsal fin and there has been much speculation in regard to its use. Herman Melville in "Moby Dick" states that the flukes of whales are tactile organs of great delicacy. I believe that the median fin of a "killer" is a tactile organ. On watching "killers" rise to the surface, this dorsal fin rises like the periscope of a submarine (Fig. 11).

Captain Wild has described to me tricks of *Orca* worthy of a crocodile. It is not easy for a "killer" to seize a seal on the edge of the ice, but he swims under it, and rising suddenly, breaks off a piece with the object of dislodging the seal. If the seal retreats crafty *Orca* follows the animal as it lumbers over the ice and breaks off successive pieces in his endeavours to seize the creature. In such tricks the dorsal fin may be a reliable tactile organ like the whiskers of cats and the feelers of cat-fishes. "Killer" whales have formidable teeth, insatiable appetites, hunt in packs like wolves, and attack the biggest whales.

FIG. 11.—*Orca gladiator*. Though Killer whales are evil-looking they glide gracefully through the sea impelled by their powerful flukes.

When Hunter died in 1793, and for many years afterwards, his skeletons of whales were the only examples existing in a museum in England.

OPOSSUMS.

Hunter kept opossums at Earl's Court, and about 1790, when he was studying the marsupials which John White brought from New South Wales, he wrote: "There is something in the mode of propagation in the opossum that deviates from all others." He kept many alive, "yet never could get them to breed." The manner in which the fœtus gets into the pouch, after puzzling naturalists for more than a century, has received a simple explanation for opossums and kangaroos. A. Goerling, of Perth, Australia, discovered in 1906 that when the naked fœtus is extruded from the vagina it is blind, but the arms are well developed, the fingers furnished with claws, and it can open and close its hands like the paws of a cat. When extruded the mother licks the birth-membranes and sets the fœtus free, which makes its way through the fur to the opening of the pouch, enters, finds a teat, and fastens itself on with the powerful lips. (Fig. 12). The naked little wanderer requires 30 minutes to make the journey, and travels through the mother's fur moving the arms alternately as in swimming and leaves a track in the fur which lasts some hours. We may believe that in this curious journey it is helped by Jacobson's organ; in the pouch the little fellow finds protection, warmth, and nourishment, and remains there till its eyes are opened, and when it has donned its fur coat, as many have seen with delight at the Zoo, the little kangaroo looks over the rim of the pouch, and gazes with curiosity on the world at large, and in a way that would have amused John Hunter. C. G. Hartman discovered that the fœtuses of the opossum, *Didelphys virginiana* find their way into the pouch in the same way as the fœtal kangaroos. (*Anat. Record*, 1920, xix., 251.)

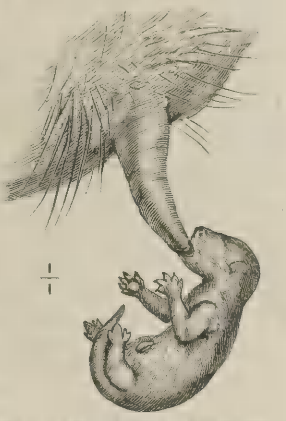

FIG. 12.—Young kangaroo hanging on the teat by its lips. (Museum, Royal College of Surgeons).

FOSSILS AND OWEN.

Belleisle and Portugal had much the same influence on Hunter that South America had on Darwin, especially in relation to geology, and had unexpected consequences, for few suspected his interest in fossils, although they were often sent to him, especially by Jenner. The discovery of the collection of fossils is one of the romances of the Museum. When Richard Owen, in 1826, started to practise as a surgeon near the College, Abernethy, concerned at the neglected condition of the Museum, induced his old pupil to assist in cataloguing it. In this way Owen became acquainted with Clift and obtained access to the collection. A few years later he married Clift's daughter, was gradually weaned from medical practice, and devoted himself to comparative anatomy. While busy with the catalogue he unexpectedly found Hunter's store of fossils, and displayed them in the Museum when it was rearranged in 1837. Startled by the number and variety of the specimens he began to work at them seriously. Nothing illustrates more thoroughly the parable of the sower than these fossils. Nearly all this seed sown by Hunter fell on stony ground, but some fell and grew in Owen's fertile brain. He dissected the bodies of animals to enable him to study fossils and become essentially a palæontologist, revelling in the reconstruction of extinct animals. The Museum contains reconstructed skeletons of huge ground-sloths; the gigantic armadillo with an "osseous coat in compartments," and a huge bird, the Moa, towering over all of them. Skeletons of sloths and armadilloes, turtles and crocodiles, with ostriches and emus, stand in rows demonstrating the truth of Owen's deductions. When these skeletons were mounted evolution and mammalian descent had not become the stock phrases of zoological zealots. To-day zoologists include extinct as well as living animals in their lists. Before Darwin classification was a mania, since Darwin zoologists persistently endeavour to bridge gaps. Hunter's fossils turned Owen's thoughts to palæontology and he led men to take an interest in animals, huge and weird, that once moved about the earth and then passed into the twilight and silence of the past.

THE ORATION.

A man who achieves greatness in any calling inspires others to follow his example. No man retains prominence unless he has impressed others to believe in him and magnify his name. Those who have been closely associated with a masterful teacher and speak well of him are often mockingly called disciples by his contemporaries. Many who during the life-time of a great investigator, or a reformer, were detractors are often loudest in appraising him when dead. When our friends are alive we hesitate to say much about them in their presence—except in after-dinner speeches. As soon as they are dead we are apt, in a paroxysm of sympathy, to overpraise their work. Hunter was in advance of his time, his contemporaries could not appreciate the value of the work, and some admirers overrate it.

The delivery of the oration is justified. It is necessary to remind men of their benefactors; even the holiest saints require to have their names preserved by shrines, chantries, cathedrals, or festivals. Are there not Saints' days in the calendar of every church—Protestant, Greek, or Roman? Æsculapius had two famous sons; of these Machaon healed injuries, and Podalirius could recognise what was not visible to the eye and tended what could not be healed. They served with the army in the Trojan war. Podalirius returning from the war was wrecked at Caria, Asia Minor. He had the good luck to cure a princess of falling sickness (probably hysteria) and in consequence acquired a great reputation. The Carians after his death built a temple in his honour and paid him divine honours. This temple has long since disappeared, but his effigy survives on the College seal (Fig. 13).

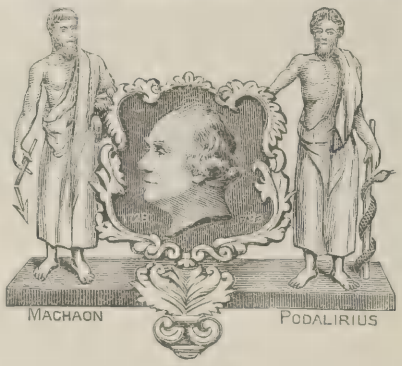

FIG. 13.

The essential work of Hunter's life was the useful specimens he prepared and left for successors. These specimens, safeguarded by faithful Clift, catalogued by sagacious Owen and Paget, and such able curators as Flower and Shattock, are now in the care of Keith, who lacks none of Hunter's enthusiasm but totally eclipses him in the art of expedition. The Museum was never in safer custody.

If I could believe the soul of man survives the dissolution of his body, I would believe the spirit of John Hunter haunts the galleries of this wonderful Museum, but I do believe his *influence is a quickening spirit among surgeons to-day.*

A Lecture

ON THE

PHYSICO-CHEMICAL MECHANISM OF CELL-RESPIRATION.

Delivered at the University of Cambridge

BY OTTO MEYERHOF,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF KIEL.

To speak here concerning cell- and tissue-respiration and the exchange of energy in muscle would seem to require boldness on my part, for I am well aware that, to use your own saying, I am only "bringing coals to Newcastle." But if in spite of this fact I undertake the task of doing so, I must first state briefly which problems seem to me most vital with regard to general cell-respiration. Respiration is no mere external attribute of living matter; it is a central life-process, supporting the entire complicated machinery of the living being.

If we desire to reduce the processes of life to physical and chemical terms, we must inquire as to what it is that distinguishes respiration from the chemical reactions of the inorganic world. There seem to me to be two more important points of difference. The substances broken down and mainly oxidised in the animal body are not actually in equilibrium with the oxygen of the air; they are in a false equilibrium, for on the removal of impediments to reaction—for example, under sufficient rise of temperature—they yield, with oxygen, carbon dioxide, water, sulphuric acid, ammonia, &c.

Such impediments prevent protein or sugar in aqueous solution from being burnt by the oxygen of the air outside the organism. What are the circumstances which in the case of the cell remove resistance to reactions and increase their velocity to the height of oxygen respiration? The general answer that it is done by cell enzymes or catalysts cannot satisfy us. First, we want to see their existence demonstrated; and secondly, we have to do with special chemical processes which are distinguished in other respects from the processes of inorganic nature. These work-producing chemical processes not only possess a large store of available free energy, but also put it more or less clearly at the disposal of the cell. We know that in this case energy is changed into work not by way of heat, but directly; this fact postulates a definite order in, and organisation of, the chemical process. This direct transformation requires a machine-like arrangement or structure—as seen, for example, in a galvanic element. (Of course, the transformation of heat into mechanical work in the case of the steam-engine also requires a machine-like arrangement, but there the chemical processes included in the heating of the boiler need no elaborate organisation.)

TWO PROBLEMS.

The two problems now presented—the cause of the reaction velocity of vital oxidations, and the transformation of the oxidation energy into work—are closely connected with the structural properties of the cell. The connexion is obvious as regards the transformation of energy, but there also exists a close connexion between speed of respiration and cell-structure. This fact has been strongly brought out by the investigations of the physiologist, Otto

Warburg. I wish to speak to-day of these investigations, in which I myself have taken an active part, in the Heidelberg laboratory and elsewhere.[1]

That there must exist a connexion between the solid stainable structures of the cells, and the velocity of oxidation, and even that respiration is essentially dependent on this structure, can be demonstrated in various ways. I may quote, as an example, the fact that the nucleated red blood corpuscles of birds show a much larger consumption of oxygen than the non-nucleated corpuscles of mammals. Furthermore, the younger blood corpuscles of birds, the protoplasm of which possesses structure which can be strongly stained with methylene-blue, consume more oxygen than the older ones. The result of the following experiment is still more convincing. If the nucleated blood corpuscles of birds be hæmolysed, being first frozen and then thawed out again, respiration does not decrease at all. Through the microscope it can be seen that the nuclei are intact, while the cell membrane is perforated and the hæmoglobin and fluid protoplasm are mixed; if this cytolysed cell suspension be now strongly centrifuged, two layers will be obtained—the upper layer containing the hæmoglobin and the fluid protoplasm, the lower one the solid cell particles, chiefly the nuclei. Respiration takes place entirely in this lower layer. But if the nuclei are disintegrated in a crushing apparatus, respiration ceases completely. (Over ten years ago Warburg carried out these experiments here in England by means of the cell-crushing apparatus designed by Barnard and Hewlett.)

EXPERIMENTS WITH SEA-URCHIN'S EGGS.

Another advance in the analysis of the relations of structure and respiration was made by experiments with sea-urchin's eggs, carried out for the most part by Warburg and myself.[2] If the egg is fertilised or subjected to treatment which produces an experimental parthenogenesis, the consumption of oxygen rapidly increases, as much as eight- or ten-fold, with the development of the fertilisation membrane and the organisation of the differentiating cell substance. (Quite recently Mr. Shearer found an eighty-fold increase during the very first minutes after fertilisation.) The production of carbon dioxide and heat also rises in proportion. Thus, the intake of oxygen in this instance expresses typical respiration. If the sea-urchin's eggs be destroyed by mechanical means, the result is apparently very different from that obtained with erythrocytes. The eggs can very easily be reduced to a shapeless pulp in which not even the outline of an egg is to be seen; this can be done simply by rubbing them with sand or by adding distilled water, or still more thoroughly after removal of their albuminous membrane by strong shaking of the coagulated egg-suspension. If these experiments are tried on non-fertilised eggs, the oxygen consumption does not decrease at all; it even increases a little. If, on the other hand, fertilised eggs be cytolysed, the increase of respiration, produced by the fertilisation, falls off again and the juice of the fertilised eggs now respires exactly as strongly as that of the same quantity of unfertilised eggs. This result, however, does not contradict the result obtained with the blood corpuscles of birds, as it may at first glance appear to do. The cell-pulp of the sea-urchin's eggs no longer shows structures of a coarse kind, but consists for the most part of fine granules. Here, too, it can be shown by centrifuging that the respiration is essentially dependent on these granules. But the cortical layer of the eggs newly formed during fertilisation, and all the coarser structures, disappear on cytolysis. Consequently the increase of the oxygen intake after fertilisation is abolished. Warburg was able to show, in various ways, that the cortical layer of the egg is indeed of special importance in the acceleration of oxidation: for instance, substances which can be proved not to penetrate into the egg, but to work only from the outside—e.g., caustic soda in sea-water—can considerably accelerate the respiration of the egg.

NARCOSIS OF CELL-RESPIRATION.

To leave for the present further investigation of the respiration in the cytolysed eggs of sea-urchins, I will now quote another series of experiments to show how the apparently mysterious influence of structure upon the velocity of oxidation may be interpreted. If respiring cells are put into a solution of an indifferent narcotic, their oxygen consumption will be stopped in a reversible manner. For effective narcotic concentrations we find here the same law as Overton and Hans Meyer had previously found for anæsthesia of the brain of tadpoles—that is to say, the higher members of a homologous series work in much smaller concentration. Their effective power is, therefore, increasingly larger than that of the lower members; this is indicated for Overton's anæsthesia narcosis as well as for the inhibition of respiration according to Warburg.

You all know that Overton and Hans Meyer attempt to explain this phenomenon by the rate of the lipoid solubility of these substances, or, more exactly, by the partition coefficient between the cell lipoid phase and aqueous solution. (Table I.) The higher members are more soluble in the lipoid phase and reach, therefore, the same concentration in it under smaller external concentrations than the lower members. Warburg and his co-workers, however, proved by a series of convincing experiments that the condensation in the lipoids cannot furnish the explanation for the narcosis of cell respiration—for in this connexion only that single aspect of narcosis is involved. In a determination of the manner in which a narcotic is distributed between the living cell and the surrounding solution, much more of the highly effective narcotics than of the less effective ones, under the same external concentrations, will be found in the cell. In the erythrocytes, for example, seven times as much thymol will be found in the cell as in the same volume of surrounding solution; 0·8 times as much acetone, however, will be found inside the cell as outside. If we now hæmolyse the bird erythrocytes, remove the stromata by centrifugation and determine separately the combination of thymol with the liquid and solid cell particles, the solid particles are found to combine with ten times as much thymol as the liquid particles. Finally, the combination of thymol and other higher narcotics with the solid parts is not noticeably decreased if the stromata are completely freed from lipoids by boiling for a long time in alcohol and ether. Here, therefore, it is only a question of adsorption.[3]

TABLE I.—*Rule of Homologous Series.*

Substance.	Partition coefficient oil/water (Overton).	Stopping of oxidation. Molecular concentration (Warburg).	Critical molecular concentration for narcosis (Overton).
Methyl alcohol	2 : ∞	5	0·62
Ethyl alcohol	1 : 30	1·6	0·31
Propyl alcohol	1 : 8	0·8	0·11
Iso-butyl alcohol	∞ : 12	0·15	0·045
Iso-amyl alcohol	∞ : 2	0·045	0·023
Heptyl alcohol	∞ : 0·15	0·01	—
Octyl alcohol	∞ : 0·05	—	0·0004
Acetone	slight : ∞	0·9	0·26
Methyl-ethyl-ketone	∞ : 20	—	0·09
Di-ethyl-ketone	∞ : 5	—	0·029
Methyl-prophyl-ketone	∞ : 4	0·17	0·019
Methyl-phenyl-ketone	∞ : 0·3	0·014	0·001

But that this adsorption is, indeed, the cause of the inhibition, and that thereby a new light is thrown upon the oxidation process, can be further demonstrated by more examples. At first the condensation of narcotics in the solid structural elements of the cells runs exactly parallel with their effectiveness. Indeed, the ascertained quality of the narcotics which undeniably explains quantitatively their effect upon the respiration is their power of adsorption. Traube[4] was the first to draw attention to the fact that the narcotic activity of different alcohols runs parallel with their power to lower the surface tension of water. In this lowering of the surface tension Traube saw the cause of their narcotic effect. That there can, however, be here no direct, but only an indirect connexion, is seen from the fact that the urethanes, or the substituted ureas, lower the surface tension of water considerably less than the degree which corresponds to their narcotic activity; it is rather another expression of the surface activity—the actual power of adsorption on boundary surfaces—which is here displayed. Warburg first recognised this in the precipitation of protein which occurs in the expressed juice of yeast on the addition of narcotics. The degree of precipitation runs exactly parallel with the rate of inhibition of fermentation. (I would add that alcoholic fermentation is influenced by narcotics in the same way as oxygen respiration.) Imagine, now, the fermentation enzyme in Buchner's yeast juice, the zymase, as a highly colloidal protein, and let the fermentation reaction proceed on the surface of this colloid. The inhibitory effect of narcotics can be clearly explained, according to Warburg, by the diminution of the effective surface of the enzyme, which accompanies the precipitation. As I have shown in publications on the narcotic inhibition of ferment processes,[5] we are dealing here with an exaggerated expression of the effect of narcotics. The precipitations are caused by salt, but the proteins are sensitised to aggregation by the presence of the narcotic. In the absence of salt these precipitations do not occur, though a narcotic inhibition of enzymes in the yeast extract can still be shown. Indeed, in a solution of invertase free from protein and, finally, in the case of an inorganic enzyme model, colloidal platinum, I demonstrated similar narcotic inhibitions and the validity of the rule of the homologous series, while no diminution of the number of particles could be shown in the ultramicroscope. In the accompanying chart is shown the inhibiting effects of the invertase action by alcohols. The curves show the typical shape of adsorption curves, slightly concave towards the abscissa axis. For these inhibiting effects I suggested as an interpretation, that the more strongly adsorbed narcotics drive off the substrate from the colloidal enzyme surface, but that the dispersion rate of the enzyme does not thereby undergo any change. This is obviously the case in every reversible narcosis.

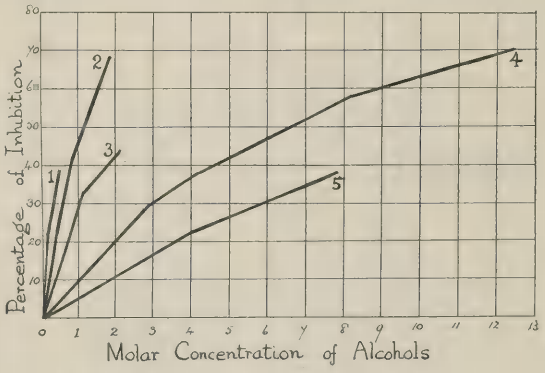

Chart showing inhibition of invertase by alcohols.

Prussic acid also inhibits respiration in a reversible manner even in a molecular concentration of 1/10,000. It is, therefore, considerably more effective than the strongest indifferent narcotics; but it is only slightly adsorbed, and its high activity must be explained in another way. The next thing is, to assume a chemical combination of prussic acid with some substance, present in a minute quantity, but yet essential for respiration, most likely with an oxidation catalyst of the cell. During the experiments with the cell pulp of sea-urchin's eggs our attention was drawn to the iron, which, as is well known, can easily enter into a complex compound with cyanide. The fact could be established that the oxidation of lecithin in presence of ferrous salt, which was discovered by Thunberg,[6] is the chief or initial process of respiration in the egg.[7] Warburg demonstrated this further in an exact analysis of the process, from which I quote only the following points: First, the sea-urchin's eggs contain per 1 g. of cell-substance about 1/500,000 mol. of iron in such a form that it yields a red colour with hydrochloric acid and potassium sulphocyanide. So it exists already in ionic form or is very easily split off as such. Secondly, an addition of iron salt, in quantities corresponding to those existing in the egg, increases the respiration considerably. Very much larger quantities do not produce any stronger effects. On the other hand, additions of the metal much smaller than the quantity present in the egg are ineffective. Thirdly, the increase of oxidation caused by the addition of iron is inhibited in the same way as the normal respiration, by cyanide and narcotics. That it is actually lecithin which is oxidised could also be proved, but I will not enter closely upon this more chemical aspect of the process.

INFLUENCES OF STRUCTURE AND IRON CONTENT IN RESPIRATORY MECHANISM.

How, then, shall we interpret the influence of structure on the one hand and of iron on the other, as coöperating in the mechanism of respiration? The hypothesis lies close at hand that respiration occurs on structural surfaces containing iron, surfaces of macro-heterogeneous, and micro-heterogeneous systems. This hypothesis, that the high velocity of oxidation of the food-stuffs in the cell is based upon a catalysis on surfaces containing iron, has been very recently confirmed by Warburg in a striking manner on a respiration model, Merck's blood-charcoal suspended in aqueous solution.[8]

It is well known that amino-acids in aqueous solution are perfectly stable when exposed to the air. If, however, animal charcoal be added to an amino-acid, the amino-acid is burnt at the temperature of the body in presence of oxygen of the air, without any other addition. It is burnt to the same end-products as in the body—e.g., cystine into carbon dioxide, sulphuric acid, and ammonia. Nitric acid is never formed as in combustion in the Berthelot bomb. Thus, in chemical respects we have obviously before us a process of oxidation very similar in the cell. It takes place on the surface of the charcoal, and is inhibited by indifferent narcotics in exactly the same way as the respiration in living cells.

In Table II. are indicated the first and last members of five homologous series, and in the second column the molar concentrations, which inhibit the oxidation rate of cystine by exactly 60 per cent. Here we see the strong decrease of the effective concentrations as we ascend the homologous series, which indicates an enormous increase of the active power in the same

Table II.—*Concentration of Narcotics Necessary to Reduce the Oxidation of Cystine by Charcoal to 40 Per Cent. of its Initial Velocity.*

Substance.	Concentration in solution, mols per litre.	Adsorbed millimols per g. charcoal (x).	Covered area $x\,(V_m)^{2/3}$.

Ethyl alcohol ..	0·32	—	—
Amyl alcohol ..	0·0015	0·87	7·9
Acetonitril	0·2	1·5	7·7
Valeronitril	0·0021	—	—

direction. Now Warburg was able to prove that the inhibition is caused by the driving off of the cystine from the surface of the charcoal. If, as in the table, the inhibition amounts to 60 per cent., we also find exactly 60 per cent. of the adsorbed cystine driven off from the charcoal, as is shown by adsorption measurements with and without narcotics. If we now determine the amounts of the various narcotics which are adsorbed by the charcoal, when in each case the oxidation velocity is reduced by a constant amount, we find the values given in the third column. It will be noticed that the quantities adsorbed very nearly agree in millimols per g. charcoal, while the surrounding concentrations differ about a thousandfold. Nevertheless, this agreement is not perfect, as the first members of the homologous series are always adsorbed a little more than the last members before they induce an equal degree of inhibition. But this last trifling deviation disappears completely when we consider that the rate of cystine removal depends obviously upon the area covered by the narcotic on the charcoal. Warburg adopts the suggestion of Langmuir, that the adsorbed substances cover the surface in a monomolecular layer. Starting from this supposition, he calculates the space occupied by each single narcotic on the surface. Since the larger molecules of the higher members need a larger space than the lower ones, the numbers of column 3 here must be multiplied with a factor for the surface covered by each single molecule, and this factor increases with the higher members. If we imagine the molecules of spherical shape and determine directly the molecular volume of each substance, we get the numbers shown in column 4 for the surface covered by each narcotic at a corresponding rate of inhibition. You will see that the number is constant within the limits of experimental accuracy. (V_m = molecular volume, x the number of millimols, so the covered surface is equal to $x\ (V_m)^{2/3}$.)

The charcoal model imitates the inhibition by cyanides as perfectly as the inhibition by narcotics. The oxidation of the cystine is inhibited by n/10,000 to n/100,000 prussic acid, though the prussic acid is only slightly adsorbed. Although, therefore, only a minimum part of the cystine is driven off from the charcoal, its oxidation is, nevertheless, completely stopped. Warburg suggests that the cyanide covers, not the whole surface, but exclusively those parts of the surface containing iron, and that the oxidation of the amino-acid only takes place on these. Indeed, the animal charcoal contains iron, about 5/1,000,000 mol per g., and the cystine oxidation is stopped by 10/1,000,000 mol of cyanide. Therefore both values correspond exactly. But iron is really necessary for the oxidation of the amino-acids. Warburg made from pure benzoic acid a charcoal preparation possessing high adsorption power, but containing only traces of iron. The cystine oxidation on this charcoal was very slight and addition of ferrous salt did not help. If, however, the charcoal was saturated with iron salt and then brought to red heat, the oxidation velocity on this charcoal reached the same value as that of the animal charcoal.

A SPECIAL INSTANCE OF SURFACE CATALYSIS.

The heating made the iron an actual component of the charcoal surface. We may imagine the structure surfaces of the living cells to be, like the charcoal surface, a mosaic of fields with and without iron. It may therefore be considered that an essential cause of the high velocity of reaction of the foodstuffs in the cell is their adsorption on the surfaces of structures containing iron. We are here dealing with a special instance of surface catalysis. Whether this is the only reason of the high velocity of reaction is still undecided. In this connexion it is a peculiar fact that for oxidation on charcoal the amino-acids occupy an especially prominent place among the stable substances. I have recently investigated the behaviour of carbohydrates on the charcoal.[10] Curiously enough, glucose is perfectly stable. On the other hand hexose-phosphoric acid is oxidised in a noticeable amount, although much less than the amino-acids. Fructose is oxidised still less, and lactic acid almost imperceptibly. In whatever way this deviating behaviour of the carbohydrates be explained, it is interesting to note that in this connexion hexose-phosphoric acid proves more easily oxidisable than glucose.

CASES OF DELAYED AND IMMEDIATE ANAPHYLACTIC SHOCK:

WITH A NOTE ON THE CIRCULATORY PHENOMENA.

BY JOHN FAWCETT, M.D. LOND.,
PHYSICIAN TO GUY'S HOSPITAL;

AND

JOHN A, RYLE, M.D. LOND.,
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL.

TRUE anaphylactic shock in human beings is of rare occurrence. Notwithstanding the innumerable instances of repeated administration of anti-tetanic, anti-dysenteric, and other sera during the war, it has been generally conceded that cases of serious or fatal anaphylaxis were few and far between. During the whole period 1914–1918 in France the second case here referred to was the only one which came under the notice of one of us (J. A. R.) of a man dangerously ill as the result of the injection of a serum. Neither before nor since that time have we met with any such alarming symptoms during serum treatment, except in the delayed case also described below.

It is recognised that man is less sensitive and less easily sensitised than the experimental animal, and it would seem that hypersensitiveness in the human subject is more likely to be an inborn than an acquired phenomenon, and that most of the recorded fatal cases have occurred in asthmatic subjects. This knowledge, however, does not render it any less important to study and record the occasional cases which occur; for this reason our experience is recounted here in some detail.

CASE 1.—A young woman, aged 23, was admitted into Guy's Hospital under the care of Mr. F. J. Steward on Nov. 5th, 1922, with a "septic" finger. Operations were performed on the 6th, 8th, 10th, and 12th, for spread of infection, amputation of the finger finally becoming necessary. On the 10th 50 c.cm. of antistreptococcal serum were given subcutaneously at the time of operation. Four days later patches of urticaria began to appear, and there was slight evening pyrexia. The local condition after the 12th progressed satisfactorily. At 4.30 A.M. on the 18th, eight days after the serum was given, patient was wakened by breathlessness. She was seen at 5 A.M. by one of us (J. A. R.) and was then sitting up in bed with "asthmatic" type of breathing. The respiration-rate was 30 per minute, expiration was prolonged and wheezing, and she was expectorating small quantities of clear mucoid sputum. Sibilant expiratory rhonchi were audible all over the chest. She was pale, and the pulse-rate was between 110 and 120 per minute. Urticaria was appearing in large patches all over the trunk and limbs; the lips, ears, and eyelids were swollen. The house surgeon, Mr. J. K. Milward, had given her an injection of liquor adrenalin 1/1000, m. 2. Within 20 minutes the asthmatic attack was over, but she felt cold and shivery, the pulse remained quick, and urticaria continued to appear. She was packed round with hot blankets and bottles, and given hot tea and lactose.

She was seen again at 8 A.M. By this time there were no asthmatic symptoms, but urticaria was still troublesome; she had vomited twice, had two actions of the bowels, and was completely pulseless. She complained of feeling "washed out" but, apart from the cutaneous irritation and swelling of the gums, made no other specific complaint; she was mentally alert, and quite rational and calm, though she had before been considerably perturbed by the respiratory distress. At 10 A.M. we saw her together; no pulsation could be detected at the wrist or ankle, or in the carotid or subclavian arteries. The heart was not then, or at any subsequent observation, perceptibly enlarged, and there were no murmurs. The impulse was readily felt, the rate was 120–140 per minute, and the sounds were of good quality. She was not cyanosed. She was warm and the temperature was rising. The capillary tide in the nail-bed was good. The question of further administration of adrenalin was discussed, but we were agreed that, with such a degree of tachycardia, and no such urgent indication as "asthma" now persisting, it would be wiser to avoid the possible overstress to the heart which a sudden rise in the blood pressure might entail. In spite of her apparently alarming condition a good prognosis was given, partly on the general impression of the patient's demeanour, the rising temperature, and the disappearance of the shiveriness of which she had at first complained, and partly on the experience of the other case referred to below. For more than 12 hours no pulse could be felt at the wrist. After 18 and 24 hours the radial pulse still could not be detected with certainty. Vomiting ceased, but the patient had some nausea and felt that she could not take fluids, except in the smallest quantities, for fear that she would be sick. She was pale and thirsty, but had a moist clean tongue, and continued to state that she felt "washed out" and intolerably tired, though she found difficulty in getting to sleep.

Treatment.—She was treated throughout with warmth, small quantities of fluid, brandy and lactose by the mouth, and six-hourly rectal administrations of 1 pint of 6 per cent. glucose. The foot of the bed was raised for a few hours, until she complained of the discomfort of the position. Sleep was secured at night with the aid of an opiate. Twenty-eight hours after the onset of the attack the radial pulse could be felt as a doubtful flicker, but not accurately counted. At the cardiac apex the rate could be readily determined as 120–130 per minute, but the sounds were not so clear as on the previous day. She now complained of acute pain in nearly all her joints. She could not open the mouth wide on account of pain in the temporo-mandibular joints, and the knees, ankles, wrists, and interphalangeal joints were similarly involved. There was no further trouble with urticaria. Aspirin was added to the rectal injections.

Recovery.—Almost abruptly at about 3 P.M. on the 19th, or about 34 hours after the first appearance of urgent symptoms, the pulse became quite good in volume and slower in rate, and from then onwards it improved steadily. By mid-day on the 20th the pulse-rate was recorded as 80 per minute. After a further 48 hours all the joint pains had disappeared, but patient complained of some deep-seated pain in the muscles of the left thigh. After this her progress was uninterrupted, except for the development of a small patch of erythema below the left knee, and later of an abscess, presumed to be metastatic, in the right buttock. On the morning of the 18th, when the "shock" symptoms were at their height, the temperature reached 102° F., but quickly fell again to normal. It rose during the period of the gluteal abscess, and became stable again after its drainage.

The remarkable feature of the case was the very late development of severe shock-like symptoms, true anaphylactic shock being usually considered as an immediate rather than a remote phenomenon. Regarding serum-sickness as the usual anaphylactic response in human subjects, this case might be viewed as an extreme exaggeration of this response, for the symptoms of "serum-shock" and "serum-sickness" were coincident. Indeed, the case suggests the essential unity of the two conditions. The early development of urticaria, on the fourth day, was an indication of hypersensitiveness. The patient was not an asthmatic subject, and there was nothing else in her history to indicate that she was previously sensitive to foreign proteins. She had at the time no recollection of ever having had serum before, but it was later elicited from her mother that she had had diphtheria 19 years previously, and that she was given antitoxin at the time. As there was no history suggesting alarming symptoms on this occasion it would seem reasonable, in spite of the long interval, to regard her as a genuine instance of sensitisation by a previous dose. We discussed the possibility of immediate shock having been averted by reason of the fact that she was under anæsthesia at the time of administration of the anti-streptococcal serum. We are, however, informed by Dr. P. P. Laidlaw that, although anæsthesia may relieve or avert bronchial spasm and so save life in the anaphylactic guinea-pig, it has little effect on similarly induced circulatory shock in dogs. Further, if the anæsthetic had merely delayed the shock it could hardly have done so for so long a period. The symptoms observed in this case were almost identical with those manifested in the following case.

Case 2.—In October, 1918, a soldier was admitted to a main dressing station with a small wound of the buttock. He was pale, cold, and pulseless; was vomiting and complaining of abdominal pains. So ill did he appear that special examinations were made to ascertain whether he might have an intra-abdominal lesion with hæmorrhage. The wound was carefully probed and found to be quite superficial. He was not aware of having sustained any other injury. Abdominal examination was negative. Within a short while urticaria appeared, and anaphylactic shock could be confidently diagnosed. The man had during his period of service received two previous prophylactic injections of A.T.S., after one of which he admitted to having "felt bad." He was examined probably within an hour or less of receiving the third dose of A.T.S., which had been given the same evening at an advanced dressing station. Mentally he was perfectly clear. He was treated as an ordinary case of surgical shock by warmth, elevation of the feet, and frequent small sips of fluid, but as after two or three hours the pulse was still impalpable he was sent down to a casualty clearing station with a special note. He there came under the observation of Major G. T. Mullally, who later reported that the man had remained pulseless for some hours, but was fit for evacuation to the base on the following day. Asthmatic symptoms were absent, and gastro-intestinal symptoms were the most prominent apart from those of circulatory failure.

In both of the cases described the general impression of the patient's condition, as judged by the mental outlook and behaviour, the heart sounds, and the recovery of body warmth, was that it was less grave than the complete absence of pulse seemed to indicate. It was largely on the experience of the earlier case that a good prognosis was given, and more active treatment withheld in the later one. We have since discussed whether we should have done better in both cases to have given frequent small doses of adrenalin subcutaneously, as the symptoms were indubitably those of an extreme fall in blood pressure, and the rapid cardiac action may have been in response to this fall. At the same time treatment on general and expectant lines was justified by the result in each instance.

Circulatory Phenomena.

The symptoms in both of the cases described suggested a profound fall in the systemic blood pressure of exceptionally long duration. Presumably the main volume of the blood must have accumulated in the splanchnic area. The absence of cyanosis, the rapid recovery and maintenance of superficial warmth, and the presence of a good capillary tide in the nail-bed would seem to exclude a capillary stagnation. There was no unusual loss of fluid by sweating, diarrhœa, diuresis, or vomiting, and the fluid intake was well maintained. The symptoms of circulatory shock persisted long after the disappearance of bronchial, cutaneous, and gastro-intestinal reactions.

At the time of writing we have not been able to find in the literature clinical descriptions of the circulatory phenomena of serum-shock in man. We are not ourselves familiar with any other condition in medicine in which "pulselessness" can persist for so long and yet a good prognosis be given. To the best of our recollection we have seen no other cases showing more than a transient pulselessness recover at all. In both cases there was reason to presume that sensitisation by a previous dose of serum had occurred. The cases emphasise the importance of inquiring of every patient about to be treated by injection of a serum whether he or she has ever before undergone a similar treatment.

THE STANDARD OF CURE IN THE TREATMENT OF GONORRHŒA.

By W. L. HARNETT, M.B.Camb., F.R.C.S.Eng.,
MAJOR, I.M.S.

No problem in the treatment of gonorrhœa is beset with such difficulties as that of deciding when a case may be passed as completely cured and when treatment be stopped. The patient usually believes himself to be cured when all symptoms have ceased and the discharge has disappeared, the persistence of a "morning drop" he looks on as of no consequence, and the advice to continue treatment is only too often neglected, until some alcoholic or other excess precipitates the inevitable relapse. By the time this happens, the gonococcus has become so deeply embedded in the many diverticula and adnexa of the urethra that its eradication is tenfold more difficult than it would have been had treatment been continuous. The recognised tests of cure by microscopical and bacteriological examination of the secretions after provocative measures, together with urethroscopic examination, are sufficiently stringent and reliable for practical purposes. The difficulty is that each test must be preceded by an interruption of treatment and, in the event of the result being positive, its resumption for a variable period, followed by a repetition of the test. In the intervals between the tests the surgeon, if there be no gleet or other sign of active disease, is rather in the dark as to what is happening.

What seems to be required is a system of treatment by means of which an accurate record of the progress of the case towards cure may be kept, so that the tests may be applied at the appropriate period, in the hope that one test may prove final. The system to be described was worked out in the venereal department of an Indian general hospital at Constantinople, and has now been in use for some two years, during which time its reliability has been demonstrated by the fact that no case has ever been readmitted for a relapse. Modifications have been introduced from time to time, and increased experience in the use of the urethroscope and other instruments has enabled better results to be obtained. Accurate records of the last 88 cases of acute gonorrhœa have been kept, and these form the basis of the present communication.

Method of Treatment.

The system of treatment is the ordinary one of urethro-vesical irrigation, with prostatic massage and such instrumental treatment as the urethroscope shows to be necessary. Inspection by the latter instrument is the test of cure for the anterior urethra. For the posterior urethra, the polymorphonuclear cells in the expressed secretions of the prostate and vesicles are roughly enumerated at regular intervals and the recorded results enable one to judge the progress of the case. All writers on the subject emphasise the importance of a careful search for gonococci, with resort to cultural investigation if none be seen. Some label a case as cured if no gonococci are thus found, and if the anterior urethra is free from infectivity. Others hold that a large number of pus cells in the mixed secretions should cause a case to be looked on with suspicion, even if no gonococci or other organism be detected. Most say that the presence of a few pus cells in the mixed secretions is of no account if no organisms are present, but are silent as to where the line is to be drawn between the suspicious cases with numerous pus cells and those which may be passed as probably cured. It was in the hope of bridging this gap that the detailed investigation of a series of cases was undertaken.

The method of treatment is as follows :—

1. After thorough examination the case, if the posterior urethra is found to be infected, is placed on urethro-vesical irrigations of potassium permanganate 1–8000, twice daily, administered by an orderly. This latter point is of special importance in dealing with Indian patients, as it would be very difficult to teach them to irrigate themselves. In any case, during the acute stage the necessary distension of the inflamed urethra with fluid is painful and is likely to be more thoroughly carried out if done by another person. For the first 68 cases of the series the routine was to commence with anterior irrigations, changing to posterior irrigations only when the acute symptoms were subsiding. Later this was changed, as it was found that there was a tendency on the part of medical officers carrying out the treatment to delay the change to posterior irrigations much too long. Anterior irrigations are now used only for cases of anterior urethritis, all cases in which the posterior urethra is found to be infected being treated with posterior irrigations from the start. The strength of the lotion used is raised, as rapidly as tolerated, to 1–2000.

2. When the discharge has thinned and the symptoms have subsided, gentle prostatic massage twice weekly is commenced. Irrigations are now given once daily only.

3. When the discharge has ceased except for a "morning drop," the anterior urethra is carefully examined with the urethroscope. Inflamed follicles are cauterised, soft infiltrations dilated with Kollmann's dilator, cystic follicles massaged over Wyndham Powell's penile dilator, or other instrumental treatment instituted as necessary. As long as a "morning drop" is present, daily irrigations are necessary. At about this time irrigations of oxycyanide of mercury, 1–4000 to 1–2000, are substituted for those of potassium permanganate.

4. When the "morning drop" has ceased the daily irrigations are stopped. Treatment now consists of massage of the prostate twice weekly, preceded by an irrigation of oxycyanide of mercury 1–2000, with which the bladder is filled. First the prostate and then the vesicles are massaged, a drop of the combined secretion is caught on a slide and carefully spread with a platinum wire if thin, with the end of a slide if thick. The slide is dried, fixed, and stained with methylene-blue. The patient passes the first portions of the bladder contents into a urine glass; the characters of the threads and plugs, if any, are noted, whether sinking, semi-floating or floating, opaque or semi-transparent, thread or comma-shaped, &c. If in doubt as to their character, a sample should be fished out and examined under the microscope. The stained slide of the mixed secretions is then examined microscopically. The whole slide is first examined under a low power and the portion most crowded with cells is selected. This portion is then examined under a 1/12 in. objective and No. 2 ocular, tube length 160 mm. Should gonococci be detected, daily irrigations of potassium permanganate are resumed, and the examination is repeated a week later. Should the slide show large numbers of other organisms, daily irrigations of oxycyanide are resumed and the examination repeated as before. Should neither of these conditions be found, the number of polymorphonuclear leucocytes in 20 or 30 fields is counted and the average number per field is recorded. Microscopic plugs (which are frequently present when none are visible macroscopically) are included in the count by totalling the number of polymorphs which they contain. Epithelial cells, lymphocytes, and other mononuclear cells are excluded from the count. Prostatic massage twice weekly is continued, and a fortnight later, at the fourth succeeding massage, the count of the secretions is repeated and the result again recorded. The patient in the meantime lives his ordinary life, except that alcohol, sexual indulgence, and such exercises as bicycling and riding are forbidden. At first the cell count will often be found to rise owing to the discontinuance of the irrigations, but later a steady improvement sets in. A reappearance of the "morning drop" or a sudden increase in the cell count is treated by the resumption of daily irrigations for a week or so. Prostatic massage twice weekly with fortnightly cell counts is continued

steadily until, in favourable cases, the urine after the massage contains no purulent plugs, and the slide shows an absence of microscopic plugs and a polymorph count of not more than 1 per field, preferably a good deal less. The patient is then ready for the final test. During successive counts the steady fall in the numbers of polymorphs will have been accompanied by the appearance of mononuclear and epithelial cells (the latter in large numbers indicate that treatment should be stopped for a while) by the reappearance of lecithin bodies, corpora amylacea, spermatozoa, and other constituents of the normal secretions.

5. For the final test all treatment is suspended for a week or ten days, during the last three days the patient takes alcohol regularly. The patient is examined after holding urine for some hours. There should, of course, be no gleety discharge obtainable. The urine after prostatic massage should be clear and any threads or plugs should be mucus only. The slide of the mixed secretions should show no microscopic plugs and the average polymorph count of 20 or 30 fields should not exceed 1 per field. The final examination with the urethroscope is then made and, if negative (as I have invariably found it to be in such cases), the patient is passed as cured.

An average count of 2 polymorphs per field may also be accepted as a probable cure, provided that a repetition of the test a week or two later, during which time no treatment has been administered, gives the same result. The presence of purulent plugs either in the urine or in the slide, or a polymorph count of more than 2 per field, is an indication for further treatment. The average period requisite to reach the above standard has been found to vary from 97 to 137 days, according to whether instrumental treatment is required or not.

A few cases remain in which it is not possible after four months of treatment to bring the patient up to the requisite standard for submitting him to the final tests. The treatment of anterior urethral lesions should be finished by now, and should be followed by instrumental treatment of the posterior urethra. An examination with the posterior urethroscope should first be made to determine whether any gross lesion, such as a polypus, is present. Usually only abnormal congestion of the verumontanum will be seen. A variety of methods of treatment have been tried, and their results judged by the effect on the polymorph counts. Posterior instillations of silver nitrate, dilatation by large sounds followed by prostatic massage, massage with a sound in situ, topical applications

TABLE I.—SUMMARIES OF RECORDS OF 22 CASES OF ACUTE GONORRHŒA TREATED IN ACCORDANCE WITH AUTHOR'S SCHEME.

Serial No.	Duration—days.	Anterior irrigation—days.	Total period of irrigation—days.	Polymorphs in prostate secretion, and day of disease. (p.f. = per field ; fs., fields.)							Final test after alcohol and suspension of treatment—days.

REMARKS, COMPLICATIONS, &c.

Case 61: Relapse due to retention cyst of a follicle treated by Kollmann's dilator. *Case 63:* Folliculitis treated by Kollmann's dilator. *Case 64:* Cystic follicle cauterised, 80th day. *Case 65:* Infiltration in bulb dilated (3rd month). *Case 33:* Epididymitis 12th day, subsided by 34th day. *Case 68:* Soft infiltration in bulb dilated (3rd month). *Case 69:* Suppurating Tyson's gland incised. Gonococci in the pus. *Case 70:* Contracted measles, about 40th day. *Case 72:* Treatment unfinished. Invalided for arthritis. Stock vaccine. *Case 73:* Kollmann's posterior dilator applied after 7th test. *Case 74:* Balanitis and phimosis. Circumcised. *Case 76:* Soft infiltration dilated in 3rd month. *Case 79:* Prolonged treatment required for hard infiltration in anterior urethra. Posterior urethra treated with Kollmann's dilator. Developed severe cellulitis of face in 4th month. *Case 80:* Epididymitis.

through Luy's posterior urethroscope, intramine injections, injections of stock gonococcal vaccines and of T.A.B. vaccine both subcutaneous and intravenous (to provoke a strong febrile reaction) have all failed to give consistent results. Some cases have benefited, others have not. Dilatation with Kollmann's posterior urethral dilator, pushed to 40 to 45 Charrière, repeated twice or thrice at intervals of four or five days, has proved the most satisfactory method of treatment. Sometimes a complete cessation of treatment for a fortnight or more will be followed by a spontaneous improvement. Nearly as good results can be obtained in these cases as in the simple cases, but the period of treatment requisite is longer. In the five cases of the present series in which instrumental treatment of the posterior urethra was necessary, the average duration of treatment was 157 days, but in three cases the final tests could not be carried out, as the patients passed from observation.

Table I. gives summaries of the records of 22 out of the 88 cases of acute gonorrhœa treated in accordance with this scheme. All the 88 cases had the posterior urethra infected on admission and gonococci in the discharge, and formed a consecutive series of cases of this character. Cases of anterior urethritis alone, those not showing gonococci, chronic cases, and cases complicated by soft chancre or severe balanitis were not included in the record as, although the same methods were used for these cases, it was considered that they would not furnish a fair test of the efficiency of the treatment. The periods in the column headed "duration" are those given in the patient's statements, which are in many cases quite unreliable; the fact that every case came in with the posterior urethra infected shows how late the cases reached hospital. Concealment of venereal disease in its early stages is only too common amongst Indian troops. The intervals between the records of the prostatic condition do not conform strictly to the scheme laid down above, owing to pressure of work on the medical officer carrying out the treatment. The final test and the one immediately preceding it was, in nearly every case, carried out by me personally.

The notation used in recording the cases is as follows:—

Polymorphs	"abundant"	means	15 and upwards	per field of 1/12 in. objective.
,,	+ + +	,,	10–15	
,,	+ +	,,	5–10	
,,	+	,,	1–5	

When the polymorphs are 1, 2, or 3 per field, the exact figure is specified. Similarly with lower figures, 1 in 2 fields, 1 in 5 fields, and so on.

The results of the final tests in this series of cases were as shown in Table II.

TABLE II.

Polymorphs per field.	No. of cases.	Intra-urethral instrumental treatment.		Average duration of treatment in days.
1 or less ..	64 (72·7 %)	Not necessary ..	47	97
		Required	17.	127
2	10 (11·3 %)	Not necessary ..	6	137
		Required	4	129
More than 2	14 (16 %)	—		121

The fact that 14 cases finished up with counts of more than 2 per field after treatment for an average period of 121 days only requires explanation. Seven of these cases (Nos. 20, 24, 25, 27, 44, 50, and 72) passed from observation, owing to their units leaving the station. In two cases (Nos. 2 and 4) treatment was discontinued, as the investigation had not then reached the stage of fixing a standard. Two others (Nos. 41 and 42) were discharged in my absence, after treatment for 122 days and 118 days respectively, with counts of + and + +, these cases should have been kept under treatment longer.

In only three cases of the series (Nos. 36, 83, and 88) was treatment abandoned with counts of 3 per field and + + after five months. A period of cessation of treatment was indicated in all these cases. Owing to unreliability of the history, no relation could be established between the duration of the disease before coming under treatment and the rapidity of cure, though such relation must exist. It will be noticed that in cases in which instrumental treatment of the anterior urethra has to be carried out, the polymorph count often keeps at a high figure whilst this treatment is going on (e.g., Nos. 53, 68, 73, 79, 83). With a focus of inflammation in the anterior urethra, over which the expressed secretions have to pass, the results of the prostatic cell counts are so unreliable, that it is not worth while recording them until the anterior urethral treatment is finished.

A considerable number of chronic cases have been treated on the same lines, but the results are disappointing. The gleet can be caused to disappear and the prostatic count considerably improved, but the standard laid down for cure was rarely attained, though this might be possible after very prolonged treatment. In examining these cases it is not always safe to rely on the results of the first prostatic massage, as the second or third massage may open up occluded foci which escaped the first time, thus causing a rise in the count. Separate examination of prostatic and vesicular secretions is often advisable. The same method may be used as a test of cure in cases where it is desired to ascertain whether an attack of gonorrhœa some time previously has completely cleared up or not. Here, too, it is necessary to remember that the result of the first prostatic massage must be received with caution. Many cases of chronic rheumatism, sciatica, and lumbago have thus been traced to their true cause, and treated in the venereal department with results more satisfactory than those previously obtained by medical treatment.

It may be objected: (1) That the method of making the films is too rough for the examinations to be a reliable index of the state of the prostate and vesicles. Provided that the same observer makes the films each time in the same manner, it is not difficult to secure films of uniform thickness, and the results of the cell counts will be comparable with each other. (2) That the standard of cure laid down is too high. This may be so, but it is a fault on the right side. That standards of cure in general use are not high enough is shown by the enormous numbers of chronic and relapsing cases in the community. (3) That no proof has been brought forward that the cases passed as cured by this standard are really cured. In a few cases cultures of the prostatic secretion were made from cases approaching the standard of cure. The prostate was massaged with the urethroscopic tube in situ and the specimen collected by passing a platinum loop down the tube. In no case was the gonococcus cultivated.

None of the cases dealt with in this communication are known to have relapsed. Had any relapse occurred the case would have been readmitted to the hospital. Several of the cases were seen again two or three months after cessation of treatment, and in all the standard was found to have been maintained. The ordinary Indian ration, on which these patients lived after the acute stage had passed, consists of highly spiced food, the consumption of which acts as a provocative. That such results could be obtained under these conditions speaks well for the method. Taking into consideration the fact that the prostatic secretion normally contains no leucocytes at all or only an occasional one, and that any residual infection of the neighbouring urethra or adnexa is certain to reinfect the prostate, the presumption that the cases which have reached the standard laid down for cure in this paper are really cured is very strong.

I am deeply indebted to Captains D. P. Bhargava, B. T. Krishnan, F. Dhunjibhoy, and W. Valladares, all of the Indian Medical Service, who worked under my direction. It is due to their careful work and accurate records that I am able to bring forward these results.

PSYCHO-THERAPEUTICS.

Opening a Discussion at the Medical Society of London on Feb. 12th, 1923.

By E. FARQUHAR BUZZARD, M.D. Oxf.,
F.R.C.P. Lond.,
PHYSICIAN TO ST. THOMAS'S HOSPITAL.

When your Council honoured me with an invitation to open a discussion on psycho-therapeutics it was not unnatural, perhaps, that I should accept the task without hesitation and without undue dismay. The subject of psycho-therapy, judging from recent literature, is so pregnant of controversy that only gentle stimulation could be required from an introductory address. It was not until the labour of writing was actually begun that I realised the enormity of the self-confidence which had led me to undertake it. The title covered such a huge field of questions which might be discussed, and many of which have been discussed almost ad nauseam, that the difficulty lay in choosing some which had perhaps escaped the attention they deserved and the consideration of which might yet be profitable.

The first questions I asked myself were: How does it come about that we are all so keenly interested in psycho-therapy at the present time? Is this interest an isolated phenomenon, or can it be regarded as part and parcel of a general and gradual change in our attitude towards the science and art of medicine? No one can deny that psycho-therapy is as old as the practice of medicine itself. It would not be an exaggeration even to say that it has been the mainstay of medical practice for centuries and that no medical man has been consistently successful in treating patients who has not, consciously or unconsciously, practised psycho-therapy. Our material ability to cope with disease was, and still is, so limited that were it not for the powerful suggestion supplied by the possession of trained knowledge, the medical profession must long since have gone under in the struggle for existence against quackery.

Growth of Knowledge Concerning Mental Disease.

The possession of knowledge concerning disease is the accumulated product of the work of the last century, when the attention of medical men was centred almost entirely on the investigation and description of mature disease, the picture presented by the patient, dead or alive, with full-grown morbid processes. Everyone was busy collecting and recording and classifying types and examples of disease, and the collector's inherent love of naming and cataloguing became an almost uncontrolled passion. Mental and physical disorders shared the same fate, and little attempt was made by the profession as a whole to understand the technique involved in the production of the pictures as they presented themselves. The amassing of all this information concerning adult disease, valuable and necessary as it was, had in the end the inevitable result of making us realise how impotent we were to cure it at that stage and how imperative it was that embryonic disorders of function should be recognised and arrested if the art of medicine were to progress. Long before this truth had become generally absorbed, and even that ideal has not yet been attained, there were isolated voices crying for its recognition. Many years before the close of the century Hughlings Jackson wrote: "The slightest departures from the standard of mental health are to be studied, and not only the cases of patients who require to be kept in asylums. Indeed, the slightest cases are the more important in a scientific investigation."

It was but a short step from the recognition of the importance of slight departures from the standard of normal health to the appreciation of the necessity for accurate, patient, and detailed history-taking in our search for correct diagnosis and treatment in both mental and physical disorders. Most physicians will agree that the longer they practise the more conscious do they become of the supreme importance of histories in arriving at diagnosis, for while physical examination may often enable us to localise the site of disease, only a careful history will allow us to interpret its pathology. If this is the case in regard to organic disease, is there any reason for supposing that it should be otherwise with those disorders which are described as functional or better still as mental?

So far as I can judge the art of history-taking, in regard to both mental and physical disorders, began to assume its appropriate prominence and to produce the discoveries which might have been expected from it, during the last 10 or 20 years of the nineteenth century. The results have not been disappointing in their relation to diagnosis, prevention, or treatment, but while on their physical side they were such as we were prepared by previous knowledge to accept without much demur, on the mental side they have met with a volume of resistance which only time and education is slowly breaking down.

Resistance Provoked by Disclosure of Sex Complex.

The historical analysis of patients suffering from tabes dorsalis led to the conclusion that the most important ætiological factor in the production of that disease was syphilis. This met with only transient and feeble opposition, because syphilis was already an accepted although distasteful factor in the origin of many morbid conditions. On the other hand, the histological analysis of some mental disorders revealed the prominent part played by sex complexes in their origin, a discovery which provoked violent resistance of a most unscientific kind. And that is the reason why we are still discussing psycho-therapeutics more than other therapeutics in spite of the fact that our interest in the early departures from the standard of normal health is as alive in relation to physical as it is in relation to mental disorders. The distinctive character of the medical profession as opposed to the hordes of healers outside its ranks is, or should be, that diagnosis precedes treatment. If this axiom is accepted it is clear that we must utilise any means which are available in our attempts to arrive at a correct diagnosis.

Value of Psycho-analysis.

Psycho-therapy, like all other measures of treatment, must depend for success on accuracy of diagnosis. In many cases of mental disorder, including neurasthenia, hysteria, phobias, obsessions, and the like, the data necessary for a diagnosis and for subsequent treatment may be arrived at by the taking of a careful history based on the conscious memory of the patient. In other cases this simple method fails and other methods requiring more time and more skill are necessary before the ætiological factors are revealed and a rational form of treatment can be insured. The experiences and insight gained by those who have practised psycho-analysis, to whatever school they may belong, has been of enormous value to the medical profession, and not only to those of us who openly support the scientific value of such inquiries. That the method in unskilful or unscrupulous hands may lead to harmful rather than to beneficial results is a charge which cannot be controverted and which, with equal truth, may be levelled against electro-therapy, vaccine-therapy, and many other therapies under similar conditions. The course of psycho-therapy was promoted more quickly than might otherwise have been the case by the recent war. The experience of treating very large numbers of minor mental disorders quickly established the fact that psycho-therapy was generally successful when all other therapeutics failed. Moreover—and this helped to reconcile some wavering unbelievers—sexual problems as ætiological agencies were brought down from a position of prominence which they were not really entitled to occupy in solitary grandeur.

Before passing on to other considerations may I submit my answers to the two questions with which I began? To take the second first—our interest in psycho-therapy is part of our general interest in treatment based on inquiry into the origins of disease and so illustrates our increasing desire to employ rational rather than empirical methods. The perhaps undue keenness with which psychotherapeutics are discussed has been stimulated by the conflict aroused in many minds between scientific inquiry and social or personal prejudices. But if psycho-therapy is to prosper and to maintain the position which is its due we must face quite frankly the difficulties which beset its path. Ultimately its success must depend on the proper education of the public mind in respect to mental disorders, and that education cannot be adequately prosecuted until the medical profession is equipped for the purpose. It cannot be denied that hitherto the newly qualified medical man or woman is very poorly equipped in this respect. His or her attention has been engrossed with organic diseases, and there has been little time to spare for what is "only functional." Little do they recognise at this stage that in practice a predominant portion of their work will concern disorders of function and for the most part perhaps disorders of mental function.

Difficulties in Teaching Psycho-analysis.

There are inherent difficulties in the teaching of psycho-therapy; unlike most forms of treatment it cannot always be practised in the open. The presence of students or graduates is sufficient by itself to abort any inquiry into a patient's mental history, and the teacher of general medicine rarely has the time or opportunity to investigate his hospital patients alone and so to supply concrete examples of his methods. And yet it would be a mistake to divorce the investigation of the physical conditions of a patient from that of his mental state. One would like to see every physician teaching general medicine give some time to the exposition of his views on psychical investigation and psycho-therapy, and at the same time find every general hospital equipped with a department for minor mental disorders. The student may learn much from his teacher's attitude towards so-called functional patients, and might probably spend a few weeks either before or after qualification in a special department.

The importance of this question of education can hardly be exaggerated. The doctor poorly equipped in the psychical aspects of his profession may not only be lacking in the power to help his patients, but may, quite unwittingly, exert a harmful influence on them. A sedulous attention to some unimportant physical abnormality or an attitude of cheery optimism as the only weapon with which to face grave psychical disturbances are equally potent causes in the production of chronic disabilities. If the medical man is able to recognise mental as well as physical suffering when he meets it, and particularly if he can discriminate between those psychical ailments which he has the power and time to alleviate and those which require special treatment and should be handed over to someone else, it is all that can be asked of him. He does this successfully with his surgical patients and there is no reason why he should not follow the same lines with patients suffering from mental disorders. But he must recognise the principle that time and skill are necessary and more fruitful of good results when spent early than when postponed until the disorder has become firmly rooted. There are so many patients who have suffered untold hardships from the advice to go away for a change, take plenty of exercise and lots of fresh air!

The question of time is the second great difficulty in the path of psycho-therapy. Time is the essence of success in the treatment of the neurasthenic and how few doctors can spare it. Complex cases require time and skill, and he who undertakes them must specialise. And here we raise the bogy of specialism. Much as we may deplore the necessity for specialism, however keenly we may scent the danger of a too narrow view in regard to a patient's condition of ill-health, we must recognise that often the skill and time of a specialist provide the only hope for the patient. I am thankful to say that we have many specialists in psycho-therapy who can be trusted to take a broad view of every case and whose training has included ample experience of humanity under other aspects of disease.

Soil and Seed.

So far I have confined myself to the consideration of practical difficulties which are obvious. Let me turn for a moment to dangers which I see ahead and which provide a snare to the unwary. Fascinated, as few can help being, by the kaleidoscopic picture presented by the workings of the human mind in response to innumerable external stimuli, let us not forget that in all probability environment will not explain all the morbid phenomena we observe. There is a tendency in some directions to disregard the soil and to pay attention only to the implanted seed. With me it is a fundamental belief that we are none of us alike from the beginning of things and that, alluring as it is to attempt the classification of human beings into types, it is far safer in the present state of our knowledge to regard each individual patient as himself and to treat him as such. Perhaps in the dim and distant future, when mental hygiene has come into its own, when the mysteries of endocrinology are laid bare, and when the decrees of heredity are capable of being interpreted, we shall each be brought up to the recognition of our individual potentialities and limitations.

Another danger to the progress of knowledge lies in the tendency to dissociate mental mechanisms from what we know of neuro-physiology. The time for correlation is not yet, but we must keep an open mind on this subject, especially in regard to the more automatic reactions of the mind and body. Dr. Hack Tuke, writing in 1894, quotes Laycock, who half a century before insisted that the true explanation of the association of ideas was to be found in the reflex function of the brain. Referring in 1844 to certain morbid mental conditions Laycock wrote: "Their detection is sometimes difficult, because the patient being keenly conscious of his infirmities will conceal them. If, however, by what is termed the association of ideas, the morbid action of vesicular neurine be brought within the current of his thoughts, he becomes utterly powerless to resist it, as much so as the electro-biologised (hypnotised) to resist the suggestions presented to their minds." Although I do not understand much about vesicular neurine there is a hint worth remembering in this buried quotation.

Other Forms of Mental Treatment.

While maintaining that psycho-therapy is the rational and scientific method of dealing with many minor disorders of the mind, it is salutary to remember that patients have obtained relief in the past from other methods of treatment and not to overlook the lesson to be learned from this fact. Rest and isolation alone, or a good holiday, have relieved many patients of mental suffering, showing that the human mind can often work out its own salvation without extraneous help, provided it is not handicapped by fatigue. We can each of us develop an anxiety state overnight which is dispelled by a few hours' sleep. This knowledge should prevent our making the mistake of jumping into psychotherapy in the case of a patient who is worn out with anxiety and insomnia. Such an error of judgment has been responsible for many failures and tends to discredit the practice of psycho-therapy. Again, we come across many patients who only suffer from an obsession or phobia when they are tired or when their resistance has been undermined by some bodily illness. True, the mental disorder is always lurking in the background ready to spring into activity when the defending forces are spent, and the patient would be more secure and much happier if the enemy were finally vanquished. At the same time these clinical experiences have their value, and go to prove that more than one factor is present in every case of disorder, mental or physical, and that successful treatment must be based on that knowledge.

Scope of Psycho-therapy.

The scope of psycho-therapy is so immense that any attempt at its definition is entirely outside my power or purpose. And yet it would profit us all if we could form an idea of its almost boundless possibilities in some directions and its limitations in others. The former constitute the fields of the specialist who has the patience and skill to unravel what appear to be inextricable tangles in the human mind, and to so readjust conflicting yet component parts that some sort of harmony is restored. The time will come when he will be able to tell us with authority what disorders he can justifiably expect to cure and what lie outside his domain. Probably he is already justified in claiming as his own the field of anxiety states, hysteria, obsessions, phobias, and many tics, but, speaking for myself and probably for others, his views on the efficacy of psycho-therapy in relation to such conditions as spasmodic torticollis and the occupation neuroses would be instructive and interesting. We know, too, that he is often called upon to try his hand with patients suffering from the milder degrees of manic-depressive insanity, and sometimes is asked to tackle epilepsy. These two disorders are mentioned in particular because they serve to illustrate the supreme difficulty underlying any estimation of therapeutic results. In mild cases of manic-depressive insanity one knows from experience that the phase of depression will almost invariably terminate of itself provided the patient is well cared for. Does the psycho-therapeutist claim that he can in any way shorten that phase? Similarly with epilepsy; it is notorious among those who have had a large experience of this disease that any change of treatment, however apparently futile, is often attended by a longer or shorter remission of symptoms. Can psycho-therapy claim more?

Before concluding may I refer briefly to the scope of psycho-therapy in face of organic disease? This is a field which must needs be cultivated by every practitioner of medicine if he is to avoid mortifying failures and the neglect of which is responsible for the prolonged life of quackery. The area covers the whole of internal medicine, but I will take my concrete examples from organic disease of the nervous system. A patient previously active and in good health develops a paralysis of his lower extremities and quite accurately a diagnosis of disseminated sclerosis is made. The inexperienced doctor will shake his head and hint at an incurable and progressive disease of the spinal cord—"Massage may be tried, but is not likely to do much good." Under such auspices it will not do much good and the patient quite naturally seeks the help of an osteopath who rapidly finds a vertebra out of place and promises a cure. While full of hope, and undergoing quite ignorant treatment, the patient makes the recovery which adequate knowledge on the part of his doctor might have foretold and which he could have promoted by legitimate physical and psychical treatment. Another patient develops the characteristic symptoms and physical signs of paralysis agitans. His doctor recognises the condition, and, having some insight into what is passing through the patient's mind, frankly assures him that, although his complaint cannot be cured, it does not lead to the horrors which are associated with the name paralysis nor to any impairment of his mental faculties. It will make him slow and less active, but if he makes up his mind to ignore this he will be surprised to find how little the disease will interfere with his enjoyment of life. If, on the other hand, he seeks cures from massage, from electricity, from osteopathy, or from Coué he will only encounter one disappointment after another and hopeless mental depression will be superadded to physical disability. May I submit that these examples illustrate the psycho-therapy which we may all aspire to practise, and further they demonstrate that psycho-therapy depends for its success not always on deep psychological learning, but inevitably on the ability to understand human nature combined with knowledge and experience of the natural history of disease.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

A meeting of this section was held on Feb. 7th, Mr. James Berry, the President, in the chair.

Mr. G. Grey Turner read a paper on

Partial Hepatectomy.

He described a case in which a sessile adenoma weighing 2 lb. 2 oz. was successfully removed from the liver by incisions extending far back into the liver substance. The patient was a boy, aged 13 years, admitted to the Newcastle-upon-Tyne Royal Victoria Infirmary on Feb. 27th, 1921, complaining of a lump in the right side of the abdomen, first noticed after an attack of pain ten days previously. His general health up till that time had been excellent; there had been no vomiting; bowels were regular, and stools normal. There were no urinary symptoms. Examination revealed a large lobulated mass in the right side of the abdomen, visible as well as palpable, extending from just below the costal margin to near the middle line, and as low as the umbilicus. There was dullness on percussion continuous with that of the liver in front and of the kidney behind. The mass was not tender and there was no ascites. The urine contained a trace of albumin. Exploratory operation with a diagnosis of renal sarcoma was decided upon. At operation a large lobulated tumour arising from the right lobe of the liver was found. The tumour had not the appearance of a gumma and was thought to be a tumour of a simple nature. A frozen section was reported to show a tumour of liver cells "possibly not very malignant"; careful examination showed that its removal by a V-shaped resection of liver, with the gall-bladder in the wedge, with its apex at the cystic duct was possible, and this operation was performed. After ligation of the cystic duct and vessels a light stomach clamp was applied to the tumour side of the proposed incision. A series of interlocking sutures of thick catgut were then passed deeply into the liver substance parallel to and on the proximal side of the proposed incision and tied. An incision was made on one side of the tumour and branches of the hepatic artery caught and tied, venous oozing being controlled by pressure. A similar proceeding on the other side of the tumour enabled it to be removed. The edges of the wound in the viscus were approximated by four interrupted catgut sutures which included the hæmostatic rows of sutures. Some oozing from the under surface of the liver posteriorly persisted; some gauze was packed over this area, a rubber drainage-tube passed to the stump of the cystic duct, a strand of rubber tissue left to protect the hollow viscera from the gauze packing, and the abdomen closed, whilst 10 oz. of gum saline solution were infused intravenously. The patient made a good recovery.

Pathology.

The mass removed, which weighed 46 oz. (the normal weight of the liver in a boy of this age being about 40 oz.), contained a growth of a pale yellowish-green colour with hæmorrhagic staining in places. The surface was divided by deep furrows into lobules. The tumour appeared to be invading the liver substance, although there was a line of demarcation plainly visible. A summary of the microscopic examination by Dr. A. F. Bernard Shaw was as follows: "The appearances here are those of a true liver-cell tumour of unusual type. While the tumour cells are obviously of a hepatic origin, they are atypical in structure and arrangement. There is evidence of both direct and mitotic division, and multi-nucleated forms are seen. Though the tumour cells are actively secreting bile—no bile-ducts are found in the substance of the growth. No evidence of tumour cell emboli was seen. Sections of the lymph gland, obtained from near the gall-bladder, show no metastases. On the whole the appearances point to an unusual type of hepatic adenoma in which, however, the cells are unusually aberrant.

After-history.—On Oct. 28th, 1921, the boy was very well. In January, 1923, 22 months after operation, he was in excellent health and hepatic function tests by Dr. George Clark indicated a normal function.

Mr. Grey Turner described other cases in which he had resected considerable portions of liver substance with encouraging results.

Indications for Partial Hepatectomy.

The indications for partial hepatectomy were comparatively few. The speaker's experience led him to believe that when malignant disease of the gall-bladder was recognisable by the naked eye no operative procedure would be curative; and partial hepatectomy was, in his opinion, unjustifiable in an operation which was merely palliative. Direct extension of a malignant growth of the stomach or colon was, he thought, an occasional indication when the tumour was otherwise operable. A tongue-shaped portion of liver bearing a hydatid or simple cyst invited excision, but partial hepatectomy was inadvisable as a routine operation for hydatid cyst in the ordinary case. Angiomata, solitary adenomata, and localised primary (and occasionally secondary) tumours of malignant nature might be dealt with in this way when the local conditions were such as to permit clean excision. Granulomata, and especially gummata, had been frequently excised under the mistaken belief that they were malignant. Gummata would be recognised by the naked eye; they were smaller than malignant nodules, their surface rounder and not umbilicated. Riedl's lobe had been excised, but this was rarely justifiable.

Methods of Controlling Hæmorrhage During Operations on the Liver.

Formerly the only method available was the extraperitoneal treatment of the stump when the mass removed was sufficiently pedunculated. This plan should not be despised, although the ideal plan was to carry out the resection and repair of the liver followed by complete closure of the abdominal wound. Hæmorrhage during the liver incision might be temporarily controlled by several methods, compression of the vessels in the free edge of the lesser omentum either by the fingers or a clamp, or by manual compression of the liver substance on either side of the incision by an assistant. Clamps might also be used, but often crushed the liver tissue severely. An elastic ligature such as a piece of rubber tubing passed deeply through the liver tissue by means of a suitable introducer and tied in such a way as to control the vessels to the area to be incised might also be employed, but this method interfered with subsequent suture. Lastly, the thermo-cautery might be used for making the incision, as in Keen's case. For the permanent arrest of hæmorrhage the branches of the hepatic artery should be caught and tied and large venous channels, surrounded by a purse-string suture, carefully tightened and tied. Apposition of the raw surfaces would control any further oozing. Suture of the liver was difficult owing to its friability. Mr. Grey Turner's method was a modification of that described by Van Buren Knott (*Annals of Surgery*, November, 1917) with the advantage that no special instrument was needed for the introduction of the hæmostatic stitches. Incisions in the liver must not encroach upon the hilum. Occasionally, it might be necessary to employ a gauze pack to stay oozing. In all cases drainage should be provided for, lest there be a bile leakage. In dealing with angiomata great care must be taken to cut wide of the tumour and to avoid puncture of them.

Partial Hepatectomy for Primary Carcinoma.

Mr. **GARNETT WRIGHT** described the case of a man of 60 years, whom he saw on June 21st, 1920. He had been ill for six weeks, and had suffered from pains in the upper abdomen shooting through the back and to the right shoulder; a lump had developed. He had had increasing constipation for some months, and occasional passage of bright-red blood, but had passed no mucus and had had no diarrhœa. On examination a large non-fluctuating oval mass was found on the right side of the umbilicus reaching to the costal margin. It moved freely with respiration, and on percussion was dull. The dullness was continuous with the liver dullness. Operation was performed on July 8th, 1920, when a large non-pedunculated spherical tumour was found deeply embedded in the right lobe of the liver. The gall-bladder was stretched over the left margin of the growth, which was the size of a Jaffa orange. There was a small secondary nodule in the liver substance, but no other growths were discovered. Mr. Wright considered that the mass was a primary carcinoma of the liver and decided to remove it. He first divided the cystic duct, as it was necessary to remove the gall-bladder, which adhered closely to the growth. An assistant controlled hæmorrhage by pressure of hot swabs, and when the growth had been removed all large veins and arteries were caught and ligatured. It was impossible to close the gap in the liver by mass sutures; the wound was therefore packed with gauze and the abdominal wall closed. The packing was removed after three days and the patient made a good recovery except for an attack of double glaucoma, for which iridectomy was performed. He was in good health at present.

Pathology.—The specimen when hardened showed a well-encapsuled tumour, with a varied appearance, being bile-stained in places, and showing hæmorrhages and degenerations in others. The tumour was examined microscopically by Prof. H. R. Dean and recently by Dr. B. J. Ryrie and Prof. J. Shaw Dunn. They all considered it to be a primary carcinoma of liver cells. Mr. Wright said that the technique of partial resection of the liver had been chiefly concerned with the control of hæmorrhage, and various methods had been adopted to isolate the operation area. Large tumours could be removed by cutting boldly through the liver substance, bleeding being controlled by pressure with a hot swab, and the vessels subsequently ligatured. The cut surface of the liver should then be drawn together by deep sutures if possible. If not, then resort should be made to packing.

Discussion.

Mr. C. H. S. **FRANKAU** when operating in 1913 upon a case of malignant gall-bladder disease with extension to the liver had resected a considerable portion of liver. The hæmorrhage during the incision was controlled with manual compression by an assistant, and afterwards stopped by gauze pressure. An attempt to close the gap in the liver by mattress sutures failed as the sutures cut out. He therefore brought a piece of omentum through the wound in the liver and sutured the liver through this. These stitches were found to hold. The portion of omentum used was then detached from the remainder and the abdomen closed.

Mr. **PHILIP TURNER** had operated on a female patient aged 29 years exhibiting signs of severe intra-abdominal hæmorrhage upon a doubtful diagnosis of a ruptured ectopic gestation as there was no history of menstrual irregularity. The abdomen was found to be full of blood, which came from a rent three inches long in a tumour the size of a cocoanut arising from the under surface of the liver. Attempts to suture the rupture failed. He therefore excised the whole tumour through a construction at its base by means of the Pacquelin cautery. The patient, who was in a state of collapse upon admission, died shortly after operation. The tumour was reported to be an adenoma, but had very large blood spaces, from which he thought it probable that hæmorrhage had occurred first into the substance of the tumour, thus causing its rupture and the severe intra-abdominal hæmorrhage.

Mr. A. J. **WALTON** had performed a large resection of the liver upon three occasions for extension to the liver of carcinoma of the gall-bladder. The operation was quite a simple one, but he was now inclined to doubt whether it was justifiable for that condition, since all three of his patients had died; one of a cardiac condition shortly after operation, and the others more remotely from secondary deposits. Hæmorrhage during incision was controlled by the hands of an assistant, and the raw surfaces subsequently brought together by a simple form of mattress suture combined with a suture through the upper aspect of the liver, which included the two loops of the mattress suture when tied. He had not experienced any difficulty owing to sutures cutting out, as he employed thick catgut and was careful to obtain a good grip of the capsule with each stitch. This form of suture by procuring good apposition of the raw surfaces had rendered the ligature of individual vessels unnecessary.

Mr. **FRANK KIDD** in July, 1911, had found at operation a tumour of the liver in a case hastily diagnosed in the early morning as one of appendix abscess. He excised the tumour and closed the wound in the liver, employing a form of suture resembling that described by Mr. Grey Turner. The tumour, which to the naked eye resembled a Grawitz's tumour, was reported to be an adenoma of the liver.

Mr. H. S. **SOUTTAR** in January, 1921, operated on a male patient, aged 45 years, who had a lump in the epigastrium, with a four months' history of epigastric pain and loss of weight. A diagnosis of carcinoma of the stomach would have been made but for the high HCl content of the gastric juice. Exploratory operation revealed a tumour of the liver, and portion of this removed at the time was reported to show the structure of a granuloma. A second operation was performed later in which a portion of liver was removed with part of the stomach and the first part of the duodenum. Hæmorrhage from the liver was controlled by manual pressure by an assistant, and the raw surfaces brought together easily by sutures of kangaroo tendon which exhibited no tendency to cut out. The patient continued to go down hill and died in June, 1921. A re-survey of the tumour made it clear that it was either a lympho-sarcoma or an encephaloid carcinoma.

Mr. C. A. R. **NITCH** operating in 1910 upon a female patient, aged 54 years, for a supposed carcinoma of the cæcum, found a yellowish tumour of a lingual lobe of the liver apparently primary. He resected the lingual lobe, using a Doyen's clamp to control the hæmorrhage and mattress sutures passed with a flat-eyed probe to close the liver wound. The patient lived for two years after the operation, and then died of recurrence of what proved to be a carcinoma of an adrenal rest.

Mr. J. E. **ADAMS** suggested the possibility of using a muscle graft for the control of hæmorrhage from the liver.

The **PRESIDENT** remarked that all the cases described had been rare and interesting. No opportunity to resect a portion of the liver had occurred in his practice until a few weeks ago when he encountered a tumour of the liver the size of an orange, apparently primary, with a number of secondary growths round it. He had not attempted its removal and still thought, after hearing the cases which had been reported at the meeting, that his case was truly inoperable. He pointed out that the anterior margin of the liver was much less vascular in the region near the hilus. In the latter situation a small rupture had in one case caused a fatal hæmorrhage.

Mr. **GREY TURNER**, in reply, said that the operation in his first case had been truly formidable, the apex of the wedge being within one inch of the hilus. Mr. Frankau's method of suture of the liver was very ingenious; the triangular ligament or a graft of fascia from the rectus sheath might be employed for the same purpose. Mr. Philip Turner's case was one where he thought the extra-peritoneal treatment of the stump might have been suitable.

Mr. **GARNETT WRIGHT**, also in reply, said that the deeper portion of the tumour which approached the hilus had in his case been shelled out.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this Society was held at 11, Chandos-street, London, W., on Jan. 26th, with Dr. **DAVID WATSON**, the President, in the chair.

Dr. D. **VINRACE** showed a male patient who contracted syphilis 30 years ago. For about 20 years he had been suffering from

Leucoplakia Affecting the Palate.

Until about two months ago the condition had remained stationary for seven to eight years. The lesion has at times responded to local treatment, but repeatedly recurred. On the left side of the tongue there was the scar of a tertiary lesion. Recently the leucoplakia had increased to such an extent that it now involved an area of the size of a five-shilling piece. The W.R. always showed a negative result, a fact which the exhibitor attributed to the test not being very reliable in tertiary syphilis. Dr. Vinrace regarded the case as being one of interest because it demonstrated how a patient can for years suffer from a condition of leucoplakia and yet be unconscious of any trouble.

Major G. **PETIT** said he had seen that day a case with periostitis on the shin, also nodes on the shin, there being a positive history of syphilis. Very little treatment produced a negative W.R. The case was positive to Stern, and to Dreyer's Sigma unit test. If Dr. Vinrace wished, he would be pleased to apply the latter test to this case. Tongue lesions due to syphilis were notorious for giving a negative W.R.—Dr. H. C. G. **SEMON** said that in his experience of these intractable cases of leucoplakia of tongue and buccal mucous membrane, the removal of carious teeth was almost invariably followed by success, even without further anti-syphilitic treatment. The present patient had many septic teeth and bad stumps. At the Royal Northern Hospital the routine treatment in such cases was to remove all septic stumps before starting anti-syphilitic treatment.—Dr. **VINRACE** stated that he gladly accepted Major Petit's offer. In spite of the negative W.R. he had treated the patient for syphilis. He expressed himself as being dentally conservative, but would see that the bad stumps and defective teeth of his patient were attended to.

Dr. H. C. G. **SEMON** exhibited a case of

Psoriasis with a Positive W.R.

The original diagnosis in 1917 in this case, of a man now aged 31, had been ringworm of the scalp. The X rays applied for the supposed ringworm resulted in a severe burn. In 1919 a ringed eruption on the body led to the diagnosis as syphilis, and the W.R. was positive. At this stage the case was referred to Dr. Semon, who diagnosed the eruption as a common ringed psoriasis of the trunk. The W.R., however, was strongly positive. Dr. Semon treated the psoriasis locally with chrysarobin and it was already much improved, and on the blood report he gave the man one injection of a new arsenobenzol preparation intramuscularly. The point he would like discussed was whether a case of psoriasis giving a strongly positive W.R. must be regarded as syphilis. This man had never had syphilis and even declared he had never run the risk of infection, and there was no suggestion of congenital syphilis; 18 per cent. of cases of psoriasis were said to give a positive blood reaction to W.R. Dr. Semon was inclined to treat the case as one of simple psoriasis, and in confirmation of that diagnosis he had on one or two finger-nails remarked the pitting, which was, in his opinion, absolutely diagnostic of psoriasis.

Dr. F. **FOWLER WARD** described a similar case of a man with a well-marked annular psoriasis, who gave a positive W.R. He was treated for some time as a syphilitic patient without effect. Under salicylic acid and eucaine the psoriasis disappeared in a few months. —Colonel L. W. **HARRISON** said he had once come across a case of psoriasis which gave a positive W.R., but no clinical signs or history of syphilis. The test, moreover, was not at that time carried out with such delicacy as to-day. During the war a number of cases which clinically were psoriasis were sent to Rochester Row for treatment, because of a positive W.R., but all except one gave a negative or indefinite W.R. on admission. The exception was sent by Dr. Whitfield for confirmation of his opinion that the case was one of ordinary psoriasis, though the W.R. was positive. Colonel Harrison and his colleagues at Rochester Row were agreed that there were no signs of syphilis, though the W.R. was strongly positive. It must be concluded that every now and then a case of psoriasis was met with which gave so strongly positive a reaction that it was misleading. In regard to the present case there might, of course, be coincident syphilis.—Dr. SEMON did not propose to continue anti-syphilitic treatment since he considered the pits in the nails pathognomonic of psoriasis.

Dr. MARGARET RORKE introduced a discussion on

Vulvo-Vaginitis.

Having stated that the various types met with afforded varying problems as to prognosis and treatment, Dr. Rorke proceeded to classify the various cases, as follows: 1. In single women: (*a*) Gonococcal vulvo-vaginitis associated with small tight vagina and sometimes with intact hymen. Treatment was difficult and discouraging owing to recrudescence after each menstrual period. (*b*) Non-gonococcal mixed infections: staphylococcal and diphtheroid were often slow to clear; generous local treatment, mixed vaccines, diathermy could be tried; sometimes dilatation and packing were needed. 2. In married women old-standing discharges with very few symptoms were often recognised only after many years as gonococcal. These were tedious to treat. 3. In pregnant women: (*a*) Gonococcal infections varied in intensity greatly, from very slight indeed to very severe distress, with pouring discharge and excoriation; sometimes there was extensive warty involvement of vulva and vagina. (*b*) Pyogenic infections: These were sometimes due to an old endometritis. Symptoms of discharge and discomfort were much more marked when a pregnancy supervened. In primægravidæ sometimes the infection was due to erosion on the cervix with secondary vaginitis from excessive sexual trauma. These cleared easily with simple antiseptics and removal of cause. (*c*) Discharge of syphilitic origin: This very important cause was not fully recognised. In a considerable number of cases purulent discharges complicating pregnancy had no other signs of syphilis, save that the pregnancy is usually small and feeble for its supposed duration. When corroborated by a strongly positive W.R. test the condition was beyond doubt, but in a few cases the W.R. was negative. In these latter, if discharge did not clear on ordinary treatment and pregnancy continued feeble, one was justified in giving anti-syphilitic treatment. In several cases the diagnosis had been confirmed by birth of child showing slight evidence of congenital syphilis, a strong W.R. being found only after delivery. 4. Vulvo-vaginitis of gonorrhœal origin in children. This was best treated by persistent daily vaginal douches by clinic nurses, followed by insertion of acriflavine pencils. Unless systematically treated these cases tended to hang on for months.

Dr. D. N. NABARRO said that in young children vulvo-vaginitis was a fairly common condition. In 1918 they had at Great Ormond-street Hospital 85 cases, in 1919 103, in 1920 111. During five years he had investigated 535 cases, and of them he found 128 were positive to the gonococcus—i.e., 24 per cent. That was more than he had expected. In children one could often hazard the diagnosis of a gonococcal infection from the greenish appearance of the discharge. A large majority of the non-gonococcal cases were due to dirt and to intestinal organisms. The tight clothes the children wore became soiled with the excreta. One saw girls aged 10 with "whites," in which diphtheroid organisms were present, almost in pure form. As to the age of incidence it was an interesting matter: two were in children of a year or under; eight were from 1 year to 18 months old; 11 of 1½ to 2 years. Half the total cases occurred at the age of 4 years or under. That was a surprise to him, as he had thought cases under 2 years of age were certain not to be gonococcal. With regard to the infectivity of the gonococcal cases, other sufferers in a family were frequently found. Some of the cases appeared to be very intractable, others became negative fairly quickly. Some cases were doubtful bacteriologically; possibly the complement-fixation test might be a help in diagnosing these cases.

Dr. A. G. SIMMINS said that at Great Ormond-street Children's Hospital they had to treat the cases entirely as out-patients. He found under douching once or twice daily by the mother, or by the district nurse, the duration of the positive swabs in gonococcal cases was three months; some cases, however, extended to 15 months. On the average, the children had been examined for six or seven months afterwards; but they tried to keep touch with them for several years. At present they were using pessaries of acriflavine specially made for children. Swabs were taken once a fortnight. Of five cases recently treated with chloramine T and pessaries, the average age had been four and two-thirds years, with positive swabs persisting just under two months. So far, these cases had only been observed during two months. In some of the children gonococcus had been found in the discharge at the end of 1 year and 15 months. Sometimes gonococci were only seen present for a week, and though the child was observed for two months afterwards, they never seemed to reappear. In the gonococcal cases the treatment was continued for about six months, the quantity gradually diminishing. The most stubborn cases were those so-called diphtheroid cases, occurring in older girls, and he would be glad of hints as to how to deal with these. Apparently the cases resembled those occurring in older and unmarried women. Had any member tried douching these or injecting glucose or other substance? In gonococcal cases the essential part of the treatment was the douching; in most cases that was all which was required, provided it could be carried out effectively. A centre was needed for these cases with a sufficient staff to carry out proper douching with the requisite frequency. At such a centre the family history could be taken and investigated, sisters and brothers examined, and the source of infection traced.

Dr. A. C. ROXBURGH said that comparatively few of these cases were seen at St. Bartholomew's Hospital. In 1920, when he analysed the statistics, the shortest case lasted 65 days under treatment, the longest 217 days, the average being 125 days. They were treated by irrigation of the vagina, by a nurse, twice a week, and painting the vagina with flavine in normal saline twice a week. Under that treatment most of them did well. In the majority of cases at St. Bartholomew's Hospital the urethra was not affected, and he had not found the cervix affected in a young child. It was comforting to know that a German worker had examined many cases who had had vulvo-vaginitis in early childhood, and in no case did he find gonococci, cervicitis, nor other ill-results of the early infection.

Major PETIT said that for male cases of gonococcal infection at Rochester Row they were at present giving acriflavine hypodermically. They had started giving it intravenously, working up to 350 c.cm. of a 1 in 1000 solution in normal saline. They had given it in saline solution up to a dilution of 1 in 25 hypodermically to mice and rabbits without ill-effect. When the dilution was more concentrated than this the animals died. The cause of death was probably poisoning by acid. It was then found that the pH value of a 1 in 15 solution of acriflavine was approximately equal to that of pure hydrochloric acid. The solution of acriflavine was then neutralised and given hypodermically in a strength of 1 in 10 without ill-effect. A colleague was at the present time working on a sodium salt of acriflavine, and had tried a bismuth salt, but the difficulty was to get it dissolved. To date they had had 64 cases, and on the average the gonococcus disappeared in 24 days, in some cases in two days. Some of the cases were early infections, others had been very chronic; none had relapsed.

Colonel **HARRISON** said that Dr. Rorke's paper disclosed valuable and conscientious work in the interests of the national health. He had been interested in the good reports following regular douching. Latterly he had felt that in gonococcal infections something in addition to vaccines was required, possibly something to improve the phagocytic production and activity. He had been fortified in that impression by the excellent results they at St. Thomas's Hospital had had in the treatment of gonococcal infections by combining the specific vaccine treatment with injections of non-specific substances into the circulation. Some had secured results by injecting turpentine, milk, and other substances; they had also employed electrargol intravenously.

The **PRESIDENT** said that traumatism due to sexual intercourse during pregnancy was a point which ought to receive more attention. At the Glasgow Lock Hospital they had had many cases of vulvo-vaginitis in children to deal with; the condition was difficult to treat satisfactorily. He laid great stress on the method by which smears were taken. In his clinic the specimens were all taken by means of a wool-wrapped probe, not a platinum loop, and were taken not from the vulva, but from the vagina. When gonococcal vulvitis was present vaginitis was also present almost invariably. In Glasgow they kept their patients as in-patients until they were free from gonococci, after which they were kept under observation as out-patients. On the average their stay in hospital was between two and three months. A treatment which was now giving somewhat better results was that described by Dr. Simmins.

Dr. **RORKE**, in reply, said they had not done the complement-fixation test for children; it had not given very satisfactory results on older patients, except where there was some other definite lesion, such as double tubes or joints. She fully agreed that constant irrigation of the cases under discussion was necessary. For some time she had not felt quite certain as to its usefulness. But she checked the treatment in the case of two girls aged 7 and 8, sisters, both having become infected from the mother. She treated one of them with long-continued douching, which was done by one of the nurses at the clinic, and the other she treated herself by painting with a 10 per cent. mercuric preparation and giving acriflavine pencils. The child being douched romped ahead of the other, and was well in half the time. As to the difficulty of knowing where the patients got the infection, it was difficult for even experienced doctors to realise the conditions of the home life of many of the people whose children attended these clinics. She was constantly receiving fresh surprises. For example, she asked a girl whether she slept alone, and she replied that she slept with the two little children of the friend with whom she lodged. Asked whether she had a towel of her own, she replied that she had not, that they all used one towel. It was surely not surprising that infection spread under such circumstances.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING of this institution was held on Feb. 1st, Prof. E. E. **GLYNN** being in the chair.

Mr. G. P. **NEWBOLT** read a note on

Myeloma of the Ischium Treated by Gouging and Radium.

Mr. Newbolt described a case of myeloma involving the tuber ischii and extending upwards towards the acetabulum and forwards along the ramus towards the pubes. The patient was a male, aged 47. X ray photographs showed the extent of the disease. At the operation the growth was freely gouged out. A few days later a tube containing 105 mg. of radium was left in the main cavity for 24 hours and in the cavity of the ramus for a second 24 hours. Four years had passed and the patient remained quite well.

Dr. C. **THURSTAN HOLLAND** showed X ray photographs which he had taken of the condition before and after operation. He described the bone changes characteristic of the condition.

Mr. R. E. **KELLY** and Dr. W. J. **DILLING** read a note on a

Case of Ergotism with Gangrene of the Toes.

It occurred in a patient of 42, a Polish Jew, who had used rye bread for many years. Dr. Dilling tested the bread and flour from which it was made and found evidence of infection by the ergot of rye. Dr. Dilling detailed his pharmacological examinations. He discussed the life-history of *Claviceps purpurea* in cereals and grasses grown on damp clayey soils during wet seasons. The chief symptoms of convulsive and gangrenous ergotism were mentioned, and the possibility of mild cases being diagnosed as gastro-enteritis was pointed out. Tabular statements showed the rapid loss of toxicity in ergot on keeping and the adulteration (1 per cent. to 10 per cent.) in various epidemics. Cases showing difference in susceptibility of individuals, even in the same family, and an instance of 0·2 g. ergot per day causing gangrene were quoted. In the present case the evidence in favour of regarding it as an instance of gangrenous ergotism was as follows: 1. The man ate exclusively rye bread, in which mycelial tissue was found microscopically, and extracts representing 46 g. and 88 g. bread produced distinct cyanosis of a cock's comb; rye from the mill contained 0·1 per cent. sclerotia and the rye grains were also partially infected; an extract of the ergot caused tonic contractions of an isolated virgin guinea-pig uterus. 2. His two attacks occurred in succeeding Novembers, when the ergot of the previous harvests would still be toxic. 3. There was no hæmorrhage on removing the toe. 4. His age, the absence of general arterio-sclerosis and of extension of the gangrene. As no further instances could be traced the case must be regarded as one of idiosyncrasy.

Mr. G. C. E. **SIMPSON** read a paper on the

Surgical Aspects of Tuberculosis of the Abdominal Lymphatic Glands.

He discussed the acute complications of this condition which usually brought the case to the hands of the surgeon. These included general and local tuberculous peritonitis following rupture of glands, abscess, acute obstruction by bands or adhesions, intussusception, rupture into the bowel, and erosion of the mesenteric artery. He considered cases complicated by acute and chronic appendicitis, chronic obstruction with serious gastric sequelæ, and tuberculous infection of the bowel. Enlarged glands might lead to strangulated hernia either by mechanical obstruction or by causing acute tuberculous peritonitis and leading to œdema and adhesion. Mr. Simpson discussed the symptoms associated with tuberculosis of one or a few groups of abdominal lymphatic glands apart from complications, and quoted a case of hæmaturia cured by removal of a large calcified gland, alluding to Thomson-Walker's work—three cases of hæmatemesis, cured apparently by removal of calcified glands; a case of chronic constipation apparently due to tuberculous glands along the vessels of the colon cured by resection of glands and ascending colon en masse; and in another case resection of the same with three feet of the terminal ileum. A number of cases with recurrent abdominal pains where no causative lesion other than tuberculous glands were found, and which improved after resection were related. The complicated nature of the operation in the later stages and the high frequency of serious complications led Mr. Simpson to plead for earlier surgical attack on the glands. The operation in such cases either of enucleation, or of resection of glands and involved intestine was safe and called only for patience. Mr. Simpson quoted 57 cases; about equal numbers showed acute complications, chronic complications, and no complications. Twelve cases were over 30 years of age, 12 under 10 years, 21 between 10 and 15 years, and 12 between 20 and 30 years.

Removal of glands was done in 43 cases and of these 15 showed no recurrence; 3 have not been traced. Two show signs of abdominal tuberculosis. In one case short-circuit and scraping out of a large abscess was done in March, 1920, and the man is still at work, but has ascites. Three cases have phthisis; two have died. In 14 cases in which removal was not attempted, two died, two have phthisis, and eight are cured. On these results he based the following conclusions: 1. That, guided by the condition of the patient, operation for the relief of acute and chronic complications of tuberculous glands in the abdomen is not complete unless not only the gland directly involved but any other group infected is removed. In widespread cases where eradication is impossible, it may be advisable to remove glands over which the peritoneum is thinned. 2. That many chronic abdominal symptoms are directly due to tuberculous glands and that removal of these is indicated where other causes for the symptoms cannot be found. 3. That even in the absence of symptoms tuberculous glands and more especially caseous glands should be removed whenever the condition of the patient allows. This is a measure of prophylaxis, and is as much indicated as the division of bands or of a normal appendix during laparotomy for other conditions.

Mr. W. H. **THOMPSON** commented on six of his cases in which abdominal tuberculosis had necessitated operation for acute intestinal obstruction. In one where perforation and massive destruction of intestine compelled him to do resection, the patient died. In four cases where involvement was so extensive and the condition of the children so poor his zeal was limited to combating the obstruction by short-circuiting the bowel. All these cases recovered and were apparently well. As those seriously ill cases had done so well he adopted the same treatment where the general condition might have permitted a more radical operation; the result was equally satisfactory. Knowing how intolerant children are to intra-abdominal liberties he believed that in such severe cases the operation of necessity (usually lateral anastomosis) ought to be the operation of choice.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

EXHIBITION OF CASES AND SPECIMENS.

THE annual meeting was held in St. Mary's Hospital, Manchester, on Jan. 19th. Prof. W. **BLAIR BELL** was elected President for the ensuing year and took the chair. The retiring president, Mr. H. **CLIFFORD**, gave his valedictory address on the history of abdominal surgery.

Dr. **LEITH MURRAY** showed three specimens of strangulation: (1) of a normal appendage, (2) of a fimbrial cyst, and (3) of a broad ligament cyst.

Dr. D. **DOUGAL** showed two specimens: (1) of spontaneous separation of one ovary and adhesion to the floor of Douglas's pouch; and (2) of a six months' fœtus with a teratomatous tumour growing from the sacral region, and suggested that these tumours might arise from the abnormal persistence of the "posterior growing point," and not be, as commonly considered, instances of conjoined twins.

Dr. **LEITH MURRAY** presented

Two Cases of Calcification.

The first case was one of calcification of an ovary in a single woman aged 31; 12 months' amenorrhœa was followed by two months' continuous bleeding, six months' menstrual excess, and a further two months' continuous bleeding. Curettage, removal of the calcareous ovary and rudimentary tube, with ventrofixation had cured the patient. Chemically the calcareous body consisted mainly of magnesium phosphate, with some calcium phosphate and traces of iron.

In the second case calcified bodies in the uterine cavity were associated with sarcoma of the ovary in a woman of 60. Three months' bleeding occurred 15 years after the menopause: a mobile, cystic tumour reached nearly to the umbilicus; the uterus was enlarged and bore a cervical polyp. After removal of the polyp and diagnostic curettage of the uterus, which appeared only to be enlarged, the abdomen was opened and the cyst, which presented the characteristics of a pseudo-mucinous cystadenoma, was removed together with the enlarged corpus uteri. On opening the uterus there were found lying loosely on the anterior wall seven flattened, glistening white, rosette-like bodies, 2·4 to 3·2 mm. diameter, and 1·8 to 2 mm. thick; these seemed to have been dislodged by the curette without leaving any indication of their original site. Chemically they consisted of calcium carbonate with traces of magnesium and iron. The ovarian tumour, on section, proved to be a short spindle-celled sarcoma. The patient was reported alive and well nine months later.

Dr. **FLETCHER SHAW** contributed two cases of

Carcinoma of the Urethra Treated by Radium.

The first case was that of a virgin, aged 45, who complained of great irritation of the vulva and painful micturition for four months previous to examination in November, 1919. A hard, red growth extruded from the urethral orifice, and extended for about ½ inch along the lumen. There were no inguinal glands. As so many of the cases previously reported had incontinence after operation, he decided to treat this case with radium, which was done in December, 1919. A year later there was some enlargement of the glands in both inguinal regions. These were removed and a few of them showed carcinomatous deposits. She was seen at intervals, and there was no further recurrence till December, 1922—three years after the first treatment with radium—when a small inguinal gland, the size of a pea, which had been overlooked at the first operation, was removed. This also contained carcinoma cells. There was no local recurrence in the urethra.

The second case was that of a married woman, aged 51, 3-para, who complained of irritation of the vulva, dyspareunia, and slight hæmorrhage for a few weeks. She had had a caruncle cauterised a few years previously. The growth was more advanced than in the other case, and consisted of a hard, red, friable mass, the size of a sixpence, extending all round the urethral orifice, and the urethra was thickened and hard for about 1 inch. No glands were found. Treatment with radium in October, 1922; two months later the growth was much diminished in size, though it had not disappeared. Patient was to have another treatment a month later. It was much too early to form an opinion as to whether the condition would entirely disappear under radium treatment, and whether there would be a permanent cure.

The **PRESIDENT** had seen an inoperable case of this description, and had also had to deal with a fistula left after previous operation by another surgeon; in that case he had been fortunate in being able to mobilise the base of the bladder and remaining urethra, and to bring them down to the vestibule with good functional result.

Dr. A. **DONALD** suggested the combination of radium and surgery as the ideal treatment in this condition.

Mr. J. **CHISHOLM** 15 months ago had a case involving the whole length of the urethra and the base of the bladder; he did a permanent, preliminary, suprapubic cystostomy, as advised by McGill of Leeds, and then removed the urethral growth and base of the bladder. As it was doubtful if the whole of the growth was removed, radium was inserted later. The inguinal glands were not invaded. Three months ago there was no recurrence, the patient was fairly comfortable and able to do a little housework.

Dr. **FLETCHER SHAW**, in reply, said that the President's remarks were particularly interesting, as he had not thought it possible to regain control of the urine after complete excision of the urethra and base of the bladder.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

JOINT MEETING OF THE SECTIONS OF MEDICINE AND SURGERY.

This joint meeting was held on Feb. 2nd, with Sir **William I. de Courcy Wheeler**, the President of the Surgical Section, in the chair.

Gastric and Duodenal Ulcers.

The **President**, in opening the discussion on this subject, said that the presence of a gastric ulcer often could not be definitely ascertained, unless an accident, such as perforation, occurred, or deformity, produced by cicatrisation, put an X ray picture beyond doubt. In cases of duodenal ulcer without deformity he had frequently obtained two X ray reports in the same case, which at first sight appeared contradictory. One report would state that there was pyloric spasm, some dilatation of the stomach, and gastric stasis. The next report that the pylorus was open, and that the stomach contents were shot through by the action of a hypertonic gastric muscle. These apparent inconsistencies could easily be explained when it was remembered that pyloric spasm frequently disappeared when the patient was put to bed on restricted diet and took alkalies freely. The spasm passed off, but the stomach remained hypertonic, and the contents were readily and forcibly propelled through an open door. It was therefore necessary to take into consideration whether a patient was at work without restriction, or in bed under medical guidance. In the small acute ulcers of females he did not think that X rays were helpful, and he did not think either that these cases were suitable for surgical interference. Excess of hydrochloric acid in the stomach was not, in his opinion, a characteristic sign of gastric ulcer; it occurred frequently in the absence of ulcer, when pyloric spasm was well marked; but ulcers in the region of the lesser curvature had no such association. It was a fallacy also to rely on the absence of hydrochloric acid in cases of suspected malignant disease. In half the cases where carcinoma arose primarily, or was grafted on a pre-existing ulcer, the presence of hydrochloric acid could be found, and, on the other hand, achlorhydria was sometimes but not frequently a feature in cases of ulcer of the duodenum. The significance of hæmorrhage was all important. They were all familiar with the hæmatemesis of biliary cirrhosis, while gastric hæmorrhage occurred frequently from pathological conditions of the pancreas, gall-bladder, appendix, and Fallopian tubes, and other organs without any lesion in the gastric mucous membrane. Oozing of blood from the stomach had been described by Hale-White under the term gastrostaxis. In renal disease it was not an uncommon symptom. He believed that it was seen during attacks of gastric crises in tabes. Capillary oozing or bleeding from arterioles quite commonly took place in all these conditions. Under the term "toxic gastric hæmorrhage" many such gastric lesions were at one time thought to be examples of vicarious menstruation. Sir William Wheeler closed with an able résumé of the questions connected with the operative treatment of so unmistakably a catastrophe as perforation. He did not believe that gastrectomy was the operation of choice in cases which were known to be non-malignant at the time of operation, but in the hands of Moynihan and Sherren the operation did not carry increased mortality. In special cases he preferred gastrectomy, the first of which he published in 1910. Once gastro-enterostomy was performed the patient again became a medical case, and with proper dieting and the administration of alkalies for three months the results would be very different from those obtained in patients allowed to go their own way.

Sir **John Moore** asked if the disappearance of pain after taking food was reliable as differentiating a duodenal from a gastric ulcer.

Dr. **J. Speares** said that personally he had never got much help from X rays in either gastric or duodenal ulcer cases, and though he always got the patients X rayed, he did not place much confidence in the results obtained. A duodenal ulcer presented peculiar difficulties if, where there was a perforation of the duodenum, it was necessary to do a gastro-enterostomy. Physicians met with numbers of cases of gastric ulcer which yielded readily to medical treatment and did not require surgery at all, but if there was any suspicion of malignancy, or if the patient did not yield to treatment, he was of opinion that they should always be operated on.

Dr. **T. G. Hardman** said that the diagnosis of ulcers by X rays depended upon (1) direct evidence—niche, or ulcer crater, accessory pocket, organic hour-glass deformity; (2) indirect evidence—spastic manifestations, retention, hypotonus, localised tenderness, a limited mobility. Of the indirect signs, the spasmodic hour-glass was the most important and was an almost certain sign of ulcer. Other secondary signs alone were sufficient to justify a diagnosis, but if correlated with clinical and laboratory evidence diagnosis might be made much more certain. Belladonna or atropine would differentiate between the intrinsic and extrinsic types of spasmodic hour-glass. The spasmodic type, when intrinsic in origin, was just as important from a diagnostic standpoint as the organic. Spasmodic hour-glass of extrinsic cause was not common, but might be due to a duodenal ulcer, gall-bladder disease, or appendicitis. When due to duodenal ulcer the spasm would not be relaxed by belladonna. Pseudo hour-glass stomach might be caused by contraction of the abdominal muscles, pressure of stomach against spine, adhesions, bands, atony, or gas in colon. The duodenal ulcer, he thought, was more difficult to diagnose radiographically than gastric ulcer. The direct sign was deformity of duodenal contour; the indirect signs included alterations in gastric tone, peristalsis, and motility, gastro-spasm, and localised tenderness over cap. The first three signs were an indication of duodenal irritation, and might be associated with conditions other than ulcer; they had frequently been found in association with mobile colon, with gall-stones, and with appendicitis. Taken in conjunction with a typical clinical picture, these were strongly suggestive of ulcer of duodenum. If the hyperactivity of stomach was found, in association with a retention and an enlarged stomach of normal outline, the diagnosis was almost certain. The coöperation of the physician was especially desirable in cases of duodenal ulcer. X ray was only part of the examination.

Mr. **Seton Pringle** was of opinion that in diagnosis of gastric ulcers, X ray reports were of the very greatest help. Duodenal ulcers were different, as their clinical history was much more definite and one could verify one's diagnosis much more directly. His treatment for gastric ulcer was—if small, cautery excision and gastro-enterostomy. If large, and in body of stomach, knife excision and gastro-enterostomy. If large and in pyloric portion, pylorectomy. He was of opinion that gastro-enterostomy alone could cure some cases of ulcer in cardia. His treatment for duodenal ulcer on anterior wall was cautery and gastro-enterostomy. If difficult of access he closed the pylorus, using the round ligament as ligature, and made a gastro-enterostomy. In gastric ulcer cases he mostly based his diagnosis on the effect of medical treatment, and in duodenal ulcer on nocturnal pain. He was of opinion that tenderness and hæmorrhage were fallacious signs.

Dr. **Rowlette** said that in practice it was often necessary to make a diagnosis of gastric ulcer without an X ray report or an operation. Unless the art of diagnosis was bankrupt, they must make practical diagnosis of cases which fell short of absolutely demonstrated certainty, and it was, he thought, in cases like this that physicians had most experience. Regarding diagnosis, he had obtained a good deal of help from X ray reports, and he would be very sorry to be deprived of the help of the radiologists. Very often cases which had no hæmorrhage and no perforation got well by medical treatment, the chief part of which, in his opinion, was rest. Recurrence might take place, but that was liable to happen after operation also. He would be interested to know if many cases of gastric hæmorrhage had proved fatal, as he thought that must be an extremely rare occurrence.

Mr. A. A. McConnell said that he had seen patients operated on for duodenal ulcer when no ulcer was found, but there was always duodenal irritation. Clinical symptoms did not tell much, as although gastric or duodenal ulcer was diagnosed, there were many other conditions which might cause the symptoms, and these had to be looked for. X ray reports had been of the greatest benefit to him in dealing with these cases, and he had found, almost invariably, that when the X ray report said there was an ulcer, at operation an ulcer was found, and when the X ray report said that the findings were only suggestive of an ulcer, at operation an ulcer was found.

Dr. M. R. Hayes said that he would like to draw attention to the fact that X ray examination was only one method of establishing diagnosis, and should not be regarded as the one thing which if it was positive was positive, and if it was negative was negative. He thought there should be more intimate coöperation between the physician or surgeon in charge of the patient and the radiologist.

Mr. Stoney said that he thought it was important to do a gastro-enterostomy at the time of operating for perforated duodenal ulcer. After gastro-enterostomy the return to feeding should be very gradual.

Dr. Crofton said that he did not think that X ray reports were any aid to diagnosis in early cases of ulcer. He was of opinion that after surgical intervention relapse might be prevented if the specific cause was isolated.

The President, in replying, said that the first joint meeting had been a great success.

BATH CLINICAL SOCIETY.

Exhibition of Cases and Specimens.

A meeting of this Society was held at the Royal United Hospital on Feb. 2nd, with Mr. W. G. Mumford, the President, in the chair.

Dr. A. B. Cluckie showed a case of orbital tumour.

Dr. R. G. Gordon showed a case of Charcot's hip-joint in a case of ? hæmatomyelia. Also a case of rheumatoid arthritis with achlorhydria gastrica which, in addition, showed signs of early pernicious anæmia and early subacute combined degeneration.

Dr. V. M. Coates showed a case of early rheumatoid arthritis with enlarged glands and achlorhydria gastrica, and discussed the importance of the latter sign.

Mr. Forbes Fraser showed a specimen of round-celled sarcoma of the breast and a case of ? gumma of the breast. Also a specimen of a large gall-stone which had given rise to very acute abdominal symptoms, and a case of a very large gastric ulcer giving rise to remarkably few symptoms, with an X ray photograph.

Dr. D. L. Spence showed a blood smear from a case of lead poisoning showing punctate basophilia.

Dr. D. A. Mitchell showed a specimen of a calcareous subpatellar bursa.

Dr. F. G. Thomson showed a specimen of a large round-celled sarcoma of the kidney.

Dr. Preston King showed an X ray of a fracture of the body of the fifth cervical vertebra which has developed tuberculous disease or secondary growth.

The President showed a case of severe double talipes and one of old arthritis of the hip of seven years' duration in a child of 10 showing signs of coxa vara.

Dr. Cluckie read a paper on the Differential Diagnosis of Acute Conjunctivitis, Acute Iritis, and Acute Glaucoma. He discussed the differential features of these diseases both with regard to objective signs and subjective symptoms. He described the correct methods of measuring the ocular tension and the pitfalls of the wrong methods.

Reviews and Notices of Books.

Colloids.

The Colloidal State, in its Medical and Physiological Aspects. By Sir William M. Bayliss, F.R.S., M.A., D.Sc., LL.D., Professor of General Physiology in University College, London. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 95. 6*s.*

In this unpretentious little book, which is sufficiently elementary to appeal to those with no more knowledge of physics than is necessary for them to pass their first medical examination, Sir William Bayliss tells the reader practically everything of any importance now known with regard to the colloidal state in its medical and physiological aspects. The author has by his own researches contributed much to our knowledge of colloids. Since the living body consists for the greater part of aqueous colloids, and since most of our food materials are of a colloidal nature, he might have been expected to assume the attitude of omniscience commonly adopted by the physical chemist who deals with biological problems. Sir William Bayliss is, however, before all else a biologist, and retains always a sense of proportion. He remains, with characteristic modesty and caution, well on the safe side in claiming little for the colloids in their application to physiology. Of the many first-class books, in different languages, dealing with various aspects of this subject which we have recently had occasion to review, this one is likely to make the widest appeal. It may serve either as an admirable introduction or as a valuable summary, and its modest compass serves to show that while lesser men require much space, a master can extract and present clearly the essence of a vast and complicated subject in a few brief chapters.

Kleines Praktikum der Kolloidchemie. Fourth edition. By Prof. Wolfgang Ostwald (University of Leipzig). With the collaboration of Dr. P. Wolski and Dr. A. Kuhn. Dresden and Leipzig: Th. Steinkopf. 1922. Pp. 174. 3*s.* 4*d.*

The course of colloid chemistry outlined in this useful little book consists of 183 experiments, most of them quite simple and requiring no elaborate apparatus. There is also, as an appendix, a list of commercial colloidal preparations obtainable in Germany. We can confidently recommend the book to teachers and others interested in colloid chemistry, on which subject the author has gained an international reputation. Though we have good English books on the subject, specialists in this country will find it useful to know on what lines Prof. Ostwald runs his course. The contents deal almost exclusively with laboratory work. The instructions for the carrying out of experiments are clear and the exercises chosen are well selected to illustrate all the fundamental properties of colloids.

Industrial Hygiene and Medicine.

By E. W. Hope, W. Hanna, and C. O. Stallybrass. London: Baillière, Tindall and Cox. 1923. With 122 figures in text. Pp. viii. × 766. 21*s.*

Industrial medicine in the past has suffered from being dealt with almost by passing reference in text-books devoted to public health on the one side, or to general medicine on the other. But in recent years growth of knowledge on the subject has been so considerable as to demand more particular exposition. Books have appeared entirely devoted to one or another aspect of industrial medicine, and now Dr. Hope and his colleagues have attempted the difficult task of bringing within the covers of one volume knowledge as regards both health and disease as affected by occupation. They have secured a great measure of success. The chapters dealing with vital statistics and general hygiene are clear, and the section on the treatment of industrial poisonings is an admirable example of condensation, covering adequately in small space metallic poisons and the effects of noxious gases. Dust as a cause of disease is well discussed; the information is up to date with regard to recent research, and much useless nomenclature has been silently committed to the grave. In this section, however, as elsewhere in the book, the authors have not resisted the temptation to introduce process illustrations which can have little meaning for the uninitiated, and are not needed by those familiar with industries. Some overlapping occurs; for example, the subject of silicosis is dealt with twice, secondly at some length in the chapter on industrial infections. Although the principal forms of industrial dermatitis are succinctly described, this section, when dealing with cancer in occupation, is inadequate. The most promising research into the causation of cancer to-day—the experimental production of cancer in animals—is based upon a clue seized from industrial cancer: yet no reference is made to this important work. Another notable omission in the book is the absence of reference to fibrositis, such as Dupuytren's contraction, caused by occupation; while the inclusion of trade neuroses, such as writers' cramp, under industrial physiology, appears to be a mistake in classification. The chapter on industrial welfare is an excellent summary, though it rather suggests the presentation of facts by the method of compilation, than the expression of vivid thoughts placed on paper by authors intimately acquainted with the conditions of industrial life.

The book throughout bears signs of painstaking preparation. Its value is enhanced by three useful appendices, in which factory legislation is summarised (unfortunately no reference is made here to mining legislation), and by a fairly good index.

GYNÆCOLOGICAL AND OBSTETRICAL PATHOLOGY.

By ROBERT TILDEN FRANK, A.M., M.D., F.A.C.S., Fellow of the American Gynæcological Society, Hon. Fellow of the New York Obstetrical Society. London and New York: D. Appleton and Co. 1922. With 388 ilustrations, of which 281 were drawn by the Author. Pp. 530. £1 1*s.*

IN this monograph the author has attempted to give information of value to the clinician and pathologist so that both will derive the greatest benefit. The book contains facts necessary for correct diagnosis and their clinical interpretation, together with an extensive bibliography in which special attention has been paid to American and English literature. The whole consists mainly of a collection of facts, not theories, and the illustrations are confined mainly to the display of microscopic sections. Chapters are devoted to technique, to the normal histology of the female generative tract, and to the relation of the normal histology to symptoms and physiological function. The various parts of the genital tract are then considered in detail and a chapter devoted to each one. Finally, consideration is given to the problems of obstetric pathology, malformation of the uterus, and the relations of the internal glands to gynæcology and obstetrics. In the chapter on the normal histology the description of the formation of the corpus luteum and the changes that occur after the rupture of the Graafian follicle are particularly fully described and illustrated, and the section dealing with the changes incident to menstruation is also very good. The thoroughness with which each condition is considered is well illustrated by that dealing with cysts in the vulva, in which no less than nine varieties are described. The vexed question of the frequency of such a condition as chronic endometritis is very clearly discussed, and the conclusion come to by the author is that chronic endometritis is an uncommon disease: because the uterus is an unusually well-drained organ and because the cyclical changes which take place each month are inimical to the continued growth of micro-organisms. Further than this, Dr. Frank thinks the condition is often confounded with endometrial hyperplasia by the pathologist, or considered as present by the clinician in cases where the endometrium is healthy which are in reality due to ovarian over-function. Possibly in some of these cases an endometrial inflammation was present; but if so it plays but a secondary and unimportant part.

All the chapters are well conceived and written, and the book contains a vast amount of information with a full bibliography which will render it of considerable value both to the pathologist and to the gynæcologist.

HUMAN CHARACTER.

By HUGH ELLIOT. London: Longmans, Green and Co. 1922. Pp. 272. 7*s.* 6*d.*

IT is relief to take up a book with a title like this and find that it does not claim to give an exposition of the "new psychology" and does not mention psycho-analysis. Mr. Hugh Elliot opens by noting that the study of character is based upon psychology, which is "merely a collection of haphazard and isolated observations, the significance of which is obscure, and must remain obscure until they have been 'explained' by physiology." Though direct references are rare yet it is plain that the author is familiar with the conceptions of modern psychology, which he has woven into his theme. At the same time he avoids the risks of definition, not hesitating, for example, to tell us that "the moral sentiment is a deep human instinct" (p. 214) and to leave the meaning to his reader's common sense, a common sense that might be puzzled to link this with an earlier remark, that "Morals are thus a more or less codified expression of social feeling," until we note that his "moral sentiment" must mean a sentiment that is not a source of morality but instinctively accepts it from the herd.

The author's main thesis is that although man is a reasoning animal he is not governed by reason but by native emotion, a seeming paradox that accords with the views of most psychologists. A realisation of its truth might well strengthen the power of reason and, as the author points out, should influence our attitude towards social and political questions. He has brought life to the dry bones of psychology and produced a pleasantly stimulating book.

LES GREFFES CHIRURGICALES.

By Dr. PL. MAUCLAIRE, Professeur Agrégé à la Faculté de Médecine de Paris; Chirurgien de l'Hôpital de la Pitié. Paris: J. B. Baillière et Fils. 1922. Pp. 312. 25*s.*

IN rather more than 300 pages Dr. Mauclaire gives a complete account of the history and progress of that branch of surgical procedure which deals with the transference of living or dead organised material from one individual, called the donor, to another, called the receiver, of whose body a true graft should become a living part. The author's wide experience of such operations enables him to offer valuable advice and to express opinions on the merits of various methods and materials

Skin-grafting, for example, in the form of rhinoplasty, appears to have been practised in India as long ago as 800 B.C. The materials which have been and may be used in grafting include all the connective tissues, as well as nerves, muscles, blood-vessels, and bone. In addition to these, glands and organs have been transferred from one living body to another. The most important factor in the estimation of the chances of a graft surviving appears to be its place of origin. The relative viability of grafts may be classified in the following order: From the receiver's own body (autoplasty); from the living body of another individual of the same species (homoplasty); from the living body of an individual of a different species (heteroplasty). Grafts taken from the cadaver, or which have been preserved in cold storage or sterilised, have, as might be expected, less prospect of survival. In the 20 "leçons" into which this book is divided Dr. Mauclaire deals with each kind of graft in turn and gives a short résumé of what has been done by others and by himself, together with judicious remarks as to the value of each procedure. Among the whole glandular organs which have been transferred from one human body to another the ovary is perhaps the most interesting. Cases are on record in which after such a transfer the receiver, both of whose ovaries but not the Fallopian tubes had previously been removed, became pregnant and bore a child. Dr. Mauclaire considers that the donor of the ovary in such a case is the real mother of the child and not the parturient receiver. If a hereditary title or property were involved it is conceivable that a court of law might have some difficulty in deciding as to the legitimacy of such offspring.

Dr. Mauclaire concludes by prophesying great advances in the future. In reading his accounts of past experiments, failures, and successes we are struck by the great part which experiments on living animals have played in the progress of this branch of surgery. In the copious bibliography at the end of the book the names of British investigators are rare.

THE MICROSCOPE.

A Practical Handbook. By LEWIS WRIGHT. Enlarged and rewritten by AUBREY H. DREW, D.Sc., F.R.M.S. London: Religious Tract Society. 1923. Pp. 287. 5*s.*

THE many microscopists to whom Lewis Wright's "Popular Handbook to the Microscope" has long been a familiar friend will welcome the new edition of this excellent manual. Dr. Drew has carried out his editorial task with skill and sympathy. The original form of the book has been faithfully preserved. The first chapters are devoted to elementary optics and the practical optics of the microscope, and contain all that the student need know. Then follow chapters on the compound microscope and its manipulation and the technique of the subject, and in these, again, the student will find sound teaching and reliable advice. It is notorious, of course, that every microscopist has his likes and dislikes, and is prepared to defend the particular instrument of his choice against all comers. Dr. Drew is no exception, and it is easy to distinguish his favourite microscope. Nevertheless, he deals faithfully and well with the various types of instruments now on the market. The last part, treating of pond life, the vegetable world, and so forth, has been enlarged and enriched with many beautiful illustrations so that it forms a real introduction to a fascinating study; the price of the book brings it within the reach of all, and we wish it the success it deserves.

SYPHILIS.

By BURTON PETER THOM, M.D. Philadelphia and New York: Lea and Febiger. 1922. Pp. 525.

THERE is much in this volume that is excellent. The author has set down in very readable fashion a quite extensive, if not too well arranged, dissertation on syphilis, treating the disease not merely from the specialists' standpoint, but also from that of the physician. The manifestations of the disease on the internal organs are well discussed, and Dr. Thom's general remarks on treatment are deserving of careful study even by those who are not in agreement with him. He specially warns against insufficient and diffident treatment. The sections dealing with the history of the disease and the animal experimentation have been unduly condensed, and the pathology also is treated too shortly. The chapter on protozoal infections other than syphilis would seem out of place here. The stages of the disease are carefully depicted, but the dermatoses cannot be well illustrated in black and white. The author wisely included a chapter on early nervous syphilis where it belongs—i.e., under the heading of the secondary stage of the disease. In regard to treatment, in which the author has been successful in giving a useful impression of the value of the different remedies, his remarks deserve careful study. But the arbitrary description and illustration of "the correct" method of vein puncture will not find universal acceptance, and the section on intraspinous therapy is hardly up to date. The book is very readable, and we can only regret that the author has not drawn more on his great knowledge of the disease, omitting certain irrelevant or redundant chapters.

ORTHOPÆDIC NURSING.

Part I.: Joint Tuberculosis. By A. G. HUNT, R.R.C. Oxford: Hall the Printer, Ltd. 1922. Pp. 54. 2*s.* 6*d.*

THIS is a pamphlet prepared by Miss Hunt, superintendent of the Shropshire Orthopædic Hospital, Oswestry, for the use of the nurses at that institution, and presumably also for orthopædic nurses in general. That this branch of nursing is a specialty is well understood by those engaged in it and by surgeons who require the services of a nurse, but is perhaps too little realised by the nursing profession in general. The standard required at Oswestry will probably astonish general nurses who read Miss Hunt's book. There they will find a detailed and complete account of the application of the splints and plaster cases used at the hospital, together with a description of many of the important symptoms and signs of tuberculous joint disease. The information may seem to be of surgical rather than of nursing importance, but if the orthopædic nurse is to be occupied in home visiting, this knowledge is necessary.

So far as the details of methods described are concerned, these apply to the particular institution for which the book is written; in other institutions other methods prevail, but the principles remain the same and the book is, therefore, of general application. The pamphlet is well prepared and copiously illustrated. It completes the section on Joint Tuberculosis and will presumably be followed by a second section on the nursing of other conditions.

JOURNALS.

THE INDIAN JOURNAL OF MEDICAL RESEARCH for January contains 21 papers, among which some are of considerable interest.—W. N. F. Woodland writes on the ligature of one renal-portal vein in the living frog, being a repetition and extension of the experiments of Gurwitsch.—W. F. Harvey completes his bacteriological and laboratory technique in this eighth section, which closes appropriately with an index.—K. S. Mhaskar summarises the main points in his diagnosis of hookworm infection, in which he comments upon the methods of mass concentration of ova, recently perfected by Clayton Lane, and also writes on the relationship between humidity and ankylostomiasis.—J. W. Cornwall contributes a highly technical paper on the salivary glands and sucking apparatus of *Cimex rotundatus.*—R. Row writes upon cultures of tubercle bacilli, with special reference to the properties of an endolipase.—S. R. Christophers discusses the structure and development of the female genital organs and hypopygium of the mosquito, and with P. J. Barraud gives a short account of the descriptive terminology applied to male genitalia of these insects.—H. E. Shortt writes on *Herpetomonas ctenocephali.* W. F. Harvey and K. R. K. Iyengar do not believe that an increase in dose will make up for loss of potency of an old vaccine.—J. A. Sinton has two papers on Indian species of phlebotomus, and gives the results of some experiments in the treatment of malaria with alkali combined with quinine.—W. F. Harvey and S. R. Christophers describe malaria research and preventive measures in the Federated Malay States and in the Dutch East Indies.—P. J. Barraud revises the culicine mosquitoes of India.—There is also an interesting preliminary note on lathyrism by A. Howard, J. L. Simonsen, and L. A. P. Anderson.

Reports and Analytical Records.

BYNOL AND BYNOTONE.

(ALLEN AND HANBURYS, LTD., BETHNAL GREEN, LONDON, E.)

WE have received from Messrs. Allen and Hanburys specimens of their Bynol and Bynotone. Bynol contains 30 per cent. by volume of pure Lofoten cod-liver oil finely emulsified with extract of malt. A commission which visited Norway to investigate the cod-liver oil industry reported very favourably on the methods employed in the factory of the firm and on the oil produced. Bynol contains considerably more cod-liver oil than many preparations of malt and oil on the market, but it has been found possible to render it palatable.

Bynotone is composed of fresh bone-marrow, yeast, nuclein, hæmoglobin, and malt extract in well-balanced proportions supplying accessory food factors. This preparation is also quite pleasant to take. Both Bynol and Bynotone, especially the former, can be recommended in the stress of cold weather.

NORIT CHARCOAL.

(BOOTS PURE DRUG COMPANY, LTD., NOTTINGHAM.)

The process for obtaining this charcoal is as follows: The vegetable charcoal is purified with boiling dilute alkali and then treated with a suitably dilute boiling acid, is then thoroughly washed with water to free it from salts, and finally heated to incandescence in vacuum. The following experiments carried out with (*a*) the activated powdered charcoal, and (*b*) ordinary charcoal B.P. give evidence of the advantages of the activated powdered charcoal over the ordinary charcoal in every case where the medicinal use of charcoal is indicated :—

—	Treated with—	
	(*a*) Activated powdered charcoal.	(*b*) Powdered charcoal.
1. Solution of mercuric chloride 1 %.	Reduced to 0·23 %.	Only reduced to 0·99 %.
2. Liq. arsenicalis B.P. 1 % As_4O_6.	,, 0·77 %.	Only reduced to 0·97 %.
3. Atropine sulphate 0·75 %.	,, 0·42 %.	No reduction.
4. Morphine hydrochloride 1 %.	,, 0·66 %.	Only reduced to 0·99 %.
5. Canal water, 40,000 living organisms per c.cm.	Reduced to sterile water.	Only reduced to 12,000 organisms.

The action of the activated powdered charcoal is rapid; in cases where the solution has been allowed to remain in contact with the charcoal for long periods and treated at intervals, the bulk of the adsorption was found to occur in the initial five minutes. In some cases, notably with mercuric chloride, the use of an increased quantity of activated powdered charcoal has resulted in the entire removal of the dissolved substance.

URODONAL AND FANDORINE.

(J. L. CHATELAIN'S LABORATORIES, 2 AND 2 BIS, RUE DE VALENCIENNES, PARIS.)

Urodonal is a preparation of hexamethylenetetramine sidonal and lysidine in the form of a granular effervescent salt. The components have long had considerable reputation in removing of uric acid and allied bodies, for which reason the drug is in quite popular use where it is required to produce a disintoxicating diuresis. The salt may be taken to the amount of three teaspoonsful a day, each teaspoonful to be taken in a tumbler of water, but, as a matter of fact, where the physical condition might make this quantity of fluid inconvenient a much smaller volume of water can be employed when it appears that the diuresis is quite as efficacious.

Fandorine is a blend of selected extracts of the ovary and mammary glands, their activity being enhanced by the addition of sedative and styptic substances. Prof. Raymond, professor of clinical medicine, Toulouse, who has made a special study of this drug, considers that it can be employed with safety in uterine congestion, remedying the symptoms without raising the arterial pressure. He justifies his observations by reporting on researches carried on in his laboratory. We fear it will not commend Fandorine to the medical profession to find among the principal indications for its use the development of the emaciated bust. The development of the female bust is a field which many persons have tilled with whom the proprietors of Fandorine would hardly desire to place themselves in competition.

"SPORTSMAN" GIN (TRIPLE DISTILLED).

(LANGLEY DISTILLERY, LTD., WORCESTERSHIRE, ENGLAND.)

A definition of gin which has been proposed is "a spirit distilled from grain, doubly rectified and then flavoured by distillation with juniper berries and other herbs." The name is a corruption of the word "Genièvre" or "Junever," the French and Dutch equivalents for juniper—the essential flavouring ingredient. Geneva, Hollands, and Schnapps are the Dutch forms of the drink. The use of gin in the pharmacopœia of the medical practitioner is well known, and the English varieties of the spirit may be unsweetened, as the sample under consideration, or sweetened by the addition of syrup. It is a spirit rarely adulterated and is probably one of the most harmless forms in which alcohol can be taken.

An analysis of "Sportsman" gin gave the following results :—

Specific gravity	0·9507
Alcohol per cent. by volume ..	40·7
Alcohol per cent. as proof spirit	71·21
Equivalent to	28·79° under proof.
Total acidity (as acetic) ..	0·02 per cent.
Volatile acid	Nil.
Extractives	0·001 per cent.

	Mg. per 100 c.cm. of absolute alcohol.
Volatile acidity	Nil.
Fixed ,, ...	60
Furfural	Nil.
Aldehydes	0·8
Esters as ethyl acetate	34

These figures are normal for a good gin. It possesses the characteristic odour and flavour of a high grade spirit of this class.

ALMATA.

(KEEN, ROBINSON AND CO., LTD. INCORPORATED WITH J. AND J. COLMAN, LTD., NORWICH).

In the Analytical Records in THE LANCET of Jan. 6th we published a report on Almata, and found it a highly satisfactory infant food. In that report we stated that "the food may be given to infants from one month old upwards." The manufacturers have now submitted to us various letters, of which the following is one, from medical men who have found that in cases where natural feeding has been impossible or medically forbidden, Almata can be given with advantage to infants from birth :—

17th January, 1923.

DEAR SIRS,—I have much pleasure in informing you of the gratifying success I have had with your "Almata" Food in feeding infants from birth—the babies thrive on it from the commencement and it is readily assimilated. I consider your "Almata" Food is the best for the artificial feeding of infants from birth as it is easily digested and the infants are free from digestive disturbance, and consequently are well contented, giving their parents the minimum of trouble and anxiety.

Yours faithfully,

——M.D., M.R.C.S.

We publish the letter because the writer appears to have read into our report a meaning which it was not meant to have, and other readers may do the same.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 17, 1923.

SUBSTITUTES OR EQUIVALENTS IN PRESCRIPTIONS.

THE Guildhall conference of bodies interested in the administration of the National Health Insurance Acts presented many features of interest, so that it became necessary to appoint a standing committee to consider and report upon many points. The conference has done useful work in bringing together representatives of those concerned in the efficiency of the service, affording an opportunity for each section, doctors, chemists, and approved societies, to display the weaknesses or ventilate the grievances existing in their respective section. Now the Acts require certain skilled services from the medical profession, and, in addition to such services, demand certain materials from the dispensing chemists. During the conference it was asserted again and again that the drugs dispensed for panel patients are of a quality inferior to those dispensed for private patients. So far as this statement goes it is obviously incorrect, since the standard quality of each individual drug is necessarily that of the British Pharmacopœia. The course of the discussion indicated that most speakers had in mind the possible employment of some cheaper substitute for a more expensive article, perhaps a proprietary preparation. And here we are face to face with an ancient difficulty, the use of "substitutes," "equivalents," or "alternatives," when a prescriber has definitely asked for something else. Across the counter it may be legitimate to suggest the employment of an article which is just as good, but when dealing with a prescription it is currently held that it is improper to make any alteration in the ingredients until the wishes of the prescriber have been ascertained. We are well aware that the prescribing of proprietaries finds many adherents, and that the practice is stated to involve annoyance to the dispenser, but, however this may be, the practice is checked by the protests of those who control expenses.

The substitution of pharmacopœial drugs or preparations for proprietary articles, which are composed of the same ingredients, in the same proportions may be legitimate if the prescriber is notified, so that he can be certain that such substantial identity is obtained. On the other hand, we are treading on more delicate ground if we suppose that the idea of substitution is to permit the employment of one article in the Pharmacopœia for another, which is assumed to have a similar, an equivalent, or an identical action. While it is clearly in order to use hexamine when the same chemical substance has been masquerading in a prescription under some other name, it would be difficult to leave the dispenser to decide what substitute or equivalent he might give in place of quinine. The dose might indicate clearly that the quinine had not been ordered for malaria, but this would not justify an assumption that any other vegetable bitter might be just as good. The prescriber must always be credited with having had some definite reason for his selection of any particular drug, and there is, we believe, no ground for the fear that he would make any difference in prescribing for private or for panel patients. The remedy he selects, rightly or wrongly, is in either case that which he believes will benefit his patient, and, further, we hold that the dispenser loyally carries out the directions, and supplies the ingredients ordered. It cannot be denied, however, that certain preparations, likes mixtures or lotions, may differ widely in the hands of different dispensers, and this is inevitable so long as the colour, flavour, or odour is left to individual discretion. It is often thought that some important ingredient has been omitted, since the solution is colourless, or almost tasteless; hence an ignorant person may be tempted into one or other of two dangerous courses: he may omit to take the medicine which would afford relief, or he may recklessly consume it in disrespectful overdoses with disastrous results. The dangers of colourless solutions are, however, so well recognised, that both private and panel patients are equally protected, even though the colour, taste, and odour may vary greatly.

In one particular it is undoubtedly true that the dispensing for the insured person has not yet reached the standard of the private patients, and it is a result of the slow permeation of the knowledge of recent therapeutic advances. In response to the dictates of pharmacology there is a widespread tendency to discard many drugs of vegetable or mineral origin in favour of vaccines, sera, and derivatives of endocrine glands. It is obviously premature for these to be adopted for the stereotyped or routine treatment of all. The position of these articles must be further consolidated, and they must be adequately defined and standardised. Meanwhile some are being used for private patients who are in a position to be able to afford them. Another feature that will probably hinder any wide extension of the range of remedies suitable for insured persons is the hypodermic method of administration so frequently involved. This entails no difficulty when large numbers, as in the army, have to undergo identical protective treatment; but, even in the largest panel, each individual should be separately dealt with, according to the nature of his malady. In conclusion, it may satisfy the quite comprehensible qualms of the approved societies to affirm that an apparent difference in many prescriptions of insured persons, and in those of private patients, is the avoidance of the names of proprietary articles in the former, and the use of their pharmacopœial equivalents. It has long since been recognised that these equivalents were introduced to ensure uniformity of standard and composition, more particularly when some dangerous drug is present. So far from being detrimental, the use of such equivalents is really a public safeguard.

◆

L'AFFAIRE SPAHLINGER.

THE position of the Spahlinger treatment has reached a stage which would be comic, were it not so supremely tragic—our French neighbours would certainly term it an *affaire*. The bactero-therapeutic institute at Carouge, near Geneva, is fully equipped with the most recent apparatus for serological and bacteriological research; it includes an experimental farm, and the whole installation would reflect credit upon a large scientific institution or university. It has been controlled and directed for ten years past by Mr. HENRI SPAHLINGER, who has trained an efficient staff in his own special methods. Precisely what his claims are, in the cure of tuberculosis, were set out in his own words in our issue of Jan. 7th, 1922. All who have visited the institute—and the visitors have been many and distinguished—have been favourably impressed with the character of Mr. Spahlinger's work and with his sincere desire to put his remedies at the disposal of mankind. The remedy has not yet reached the stage of proved value and necessity. Mr. Spahlinger himself does not pose as a clinician, and the clinical trials of his remedies have been spread over several countries and have nowhere been carried out under research conditions. It is well known that the British Ministry of Health is prepared actively to encourage the experimental trial of the Spahlinger preparations under scientific supervision, so soon as supplies of the remedy are available for the purpose, and the British Red Cross has gone so far as to vote a sum of £30,000 to enable Mr. Spahlinger to produce his remedies to a larger extent so that they may be tried in this country.

The issue being thus clear-cut, it is with the keenest regret that we have noted during the last week evidences of a press campaign to raise funds in this country on the ground that the reports already published prove beyond doubt the great national importance of the movement. A Memorandum, ostensibly prepared by several medical men as an authoritative statement of facts, contains such regrettable exaggerations as that the methods of Spahlinger make it clear that tuberculosis can be prevented, and that when the treatment is over there is no trace of the disease remaining. There is a suggestion that, had they not been prevented from doing so by the fear of "oblique advertisement" (in the sense of the General Medical Council), many important signatures would have been appended to this statement. It seems to us improper to infer the weight of medical opinion in such a way. The Ministry of Health has found it necessary to reissue a statement of its position—namely, that up to the present the Minister has neither approved, nor disapproved, of the treatment.

The Memorandum justifies the appeal for funds by the grave danger from financial pressure to which Mr. Spahlinger's work is now exposed. We can only trust that he will submit to the independent investigation of his remedy which would put him right with the medical world and relieve him of his immediate difficulties. Could some arrangement be made to carry out this investigation, with the usual controls, at one or other of the research institutes in this country, two objects would be served: (1) the money could be raised without risk of forfeit; and (2) the control would bring conviction to those among whom it is carried out. We appeal to Mr. Spahlinger in the name of humanity, no less than in that of science, to consent to this course.

◆

EFFICIENT DIAGNOSIS OF CANCER.

At the present time a number of new and hopeful methods of treatment are being brought to bear upon cases diagnosed clinically as cancer, and the proving of these methods must depend in large degree upon the certainty of the diagnosis. Surgeons in all countries for many years past have been perfecting their powers of clinical acumen to make sure that they only intervene when it is needful for them to do so and then to good purpose. In a paper read before the Nebraska branch of the American College of Surgeons, and now reprinted in a volume of Collected Papers of the Mayo Clinic,[1] Dr. William C. MacCarty attempts to answer the question: Have we, as a profession, reached our greatest efficiency in the clinical diagnosis of neoplasms? In order to determine the present degree of diagnostic efficiency Dr. MacCarty has compared the pre-operative diagnosis of a group of well-trained graduates of first-class medical schools in America and other countries with the actual condition found at operation, checked by a surgical pathologist. Confining his study to the mammary gland, on the grounds that it is easily seen and felt and a frequent site of a variety of neoplasms, he finds that surgeons are willing to commit themselves to a positive diagnosis in 78·5 per cent. of cases and unwilling to commit themselves definitely in 21·5 per cent. When clinicians are certain enough to say "malignant" they prove to be correct, Dr. MacCarty finds, 94·5 times out of 100. This, as he says, is the percentage which doctors like to quote, but it is not an index of diagnostic efficiency, for there remain the 21·5 per cent. of cases in which the clinician is unwilling to commit himself before operation. Thus the actual percentage of malignant breasts diagnosed positively by the clinician correctly becomes reduced to 77 per cent., while the percentage of benign breasts diagnosed positively by the clinician correctly is only 50 per cent. Now most surgeons have been content to operate first and to hear the pathologist's report afterwards when it is too late to guide their action. It was the late Mr. C. B. Lockwood who suggested in 1899 the plan of cutting frozen sections of every tumour at the time of operation and Mr. Ernest Shaw who worked out the details of the method. Mr. Shaw first set out his method in our columns in 1910, and in our issue for Feb. 3rd, after an experience of 23 years, he summarised his results. The delay occasioned by his presence in the operating theatre is not serious; the whole process of freezing, cutting, mounting, staining, and examining a section requires five minutes or less. Mr. Shaw has made it a rule to prepare paraffin sections to examine at leisure later, and he states that in every instance—and he is writing of 540 cases—the leisurely has confirmed the hasty picture.

The pathologist may thus be a person of some moment in the operating theatre. Suppose, Dr. MacCarty asks, you are the surgeon and have no surgical pathologist, what are you going to do with a patient who happens to be one of this 21·5 per cent.? In the whole series of 2100 cases which he studied, not one was treated too radically, and not one failed to receive a radical operation when necessary, by virtue of the fact that all the clinical diagnoses were checked at operation by a surgical pathologist. This is his answer to his own question. He then sets out certain reasons why all breast cases are not checked, and the list is worth quoting in his own words:

1. You may not have a pathologist.
2. You may not have tried to have a pathologist.
3. There may not be a pathologist near you.
4. You may think you are a great pathologist, especially a great gross pathologist, in which case you simply incise the tumour, immediately after its removal, and pass judgment.
5. You may not believe in frozen sections.
6. Your practice may not be large enough to allow you to pay a pathologist.
7. You may be depending upon the hospital to supply you with a pathologist.
8. You may have lost faith in pathologists because you have had sad experiences with men who call themselves pathologists, or with the so-called intern pathologist who happens to be sojourning in the hospital for a year or two doing everything in the categories of tissue pathology, bacteriology, serology, clinical microscopy, and sometimes roentgenology.

Dr. MacCarty himself believes that it is unfair to perform a radical operation on the mammary gland in doubtful cases, but that it is fair with our present knowledge to remove a sector of the gland-bearing structure for immediate examination. The lining of the ducts and acini of the breasts consists normally of two layers of cells; if these are present the pathologist is dealing either with a normal condition or one in which there is at most reaction to some disturbing factor. Radical operation is then unnecessary. Should the hyperplastic cells of the outer row be found to have invaded the stroma, malignant condition is present and radical operation should be performed. If after thorough microscopic examination a condition is found in which the outer cells, although hyperplastic, have not invaded the stroma, his experience indicates that the removal of the gland-bearing structure is sufficient. He has never seen recurrence after such a simple operation.

---

[1] Vol. xiii. Published May, 1922. London and Philadelphia: W. B. Saunders Company. 60s.

This is the type of service which the surgical pathologist can render. Whether the microscopical determination of malignancy is quite as simple as Dr. MACCARTY seems to imply is a question which we prefer to leave open. In the case of the breast numerous layers of cells are sometimes seen in simple inflammation; in some growths but one layer of columnar cells is present in the alveoli. Probably the most important point to determine in an early case is whether the basement membrane is or is not intact. Moreover, malignant disease of the breast is usually one of the easier forms of growth to distinguish in frozen sections. It is notoriously difficult to decide between some forms of sarcoma and inflammatory tissue even under the most favourable conditions. And on this decision may depend the amputation of a limb. Frozen sections and rapid staining can hardly solve difficulties which still vex the skilled pathologist after the whole ritual of hardening, embedding, and differential staining has been observed. Nevertheless, if all surgeons were to follow out this plan over a series of years, substantial progress might be made and an end be put to the fashion of guessing. Guessing should not be agreeable to the scientific surgeon, nor will it help to assess the value of non-surgical methods. The case for exact microscopic diagnosis of neoplasms is very strong indeed, but it would involve a large staff, and specialisation has gone on among pathologists to the extent of strictly limiting those who devote themselves to the study of morbid anatomy and histology. The method of "rapid diagnosis" has established itself to meet the emergency of the operating theatre, but it can in no way replace the careful and detailed pathological examination to which every breast, and indeed every tumour, removed by operation should be submitted. The pathologist may still be unable to suggest what course the case showing an unusual type of tumour is likely to take. Mr. SHAW'S plea is valid for a national pathological museum, where examples of every kind of malignancy may be obtained. For microscopic examination is the only really efficient control to the clinical diagnosis, and until the necessity for adequate controls is as clearly recognised by the clinician as it is by the laboratory worker the outlook for progress in diagnosis and treatment will never be as hopeful as it might.

ROYAL SANITARY INSTITUTE.—A meeting will be held on March 2nd and 3rd, in the Town Hall, Sheffield, when discussions will take place on Extraneous Matters in Food and the Prevention of Disease by Feeding, to be opened by Mr. J. Evans, city analyst, and Prof. E. Mellanby, respectively. The chair will be taken by Dr. Louis C. Parkes. On March 3rd visits will be paid to the Corporation Sewage Works, at Wincobank, and the works of Messrs. Newton, Chambers and Co., at Thorncliffe.

The annual congress will be held at Hull from July 30th to August 4th next.

Annotations.

"Ne quid nimis."

WILHELM KONRAD V. RÖNTGEN.

THE death is announced of Prof. Röntgen at Munich, in his seventy-eighth year. Born in 1845 at Zennep in Rhenish Prussia, Wilhelm Konrad von Röntgen was educated in Holland and at Zurich, where he became doctor of science in 1869. In 1885, after holding various appointments in German universities, he became professor of physics at Wurzburg, where on Nov. 8th, 1895, he discovered X rays in circumstances so well known as to render description unnecessary. Although the exact nature of these rays has not yet been ascertained, their use immediately resulted in a great advance in many branches of scientific work. The medical and surgical application of the rays first took the direction of localisation of coarse foreign bodies, as bullets, but almost immediately a dozen directions were seen in which the discovery would advance therapeutics. Apart from its medical uses, great advances in physical and industrial investigation have also been made possible by the discovery. The medical aspects of Röntgen's discovery form a story that must be told at some length later.

THE PATHS OF INFECTION.

UNTIL the last few years the accepted theory as to the dissemination of many of the infectious diseases of this country was that the victim was always inoculated from a previous case, and that the virus was conveyed from the one to the other by direct contact or some similar direct transmission, such as the breath, or by means of fomites. With small-pox it may be said that our experience accords with this theory, and that action based on the isolation of the sick from the healthy, and on disinfection, has been successful. There are certain other diseases, such as measles and chicken-pox, in which the infection also appears to be spread directly, although there is not the practical evidence of the successful application in the community of measures based on the theory. But our experience with scarlet fever and diphtheria points in the opposite direction. If the *usual* method of spread were by direct infection or through fomites, it would be reasonable to expect that prompt isolation in hospital of nearly every diagnosed case, followed by disinfection of the infected room, clothing, and bedding, which is the method practised in many of our sanitary areas, would have resulted in a great reduction in these diseases. It has been the subject of comment that there is so little evidence of any such diminution, and we understand that the practice of treating the cases in their own homes, which is being reverted to in some districts and has always been in vogue in others, results in no excessive incidence.

It is evident from such facts that, while there may be no grounds for thinking that the recognised case of scarlet fever or faucial diphtheria cannot infect a susceptible person directly, yet such direct transmission is not the ordinary way of spread. What the ordinary channel of infection may be is unknown. The knowledge of the cause of diphtheria which bacteriology has afforded has not yet led to the tracing out of this path. But it has shown that only a minority of the population is susceptible, and that the causative bacilli are to be found in many more persons in an infected community than the disease itself. The facts may be explained on the assumption that the infection is spread broadcast from one naso-pharynx to another, but that only a minority of the infected—those who lack immunity—develop the disease. This has been suggested as the mode of spread in certain other diseases like cerebro-spinal fever, which under present-day civilian conditions exhibits almost no power of direct infection; and it may well apply to scarlet fever, to which a large proportion of the population appears to be immune. In the latter disease bacteriology affords no help, and it is remarkable how meagre is our knowledge, not only as to the way in which it spreads in the community, but even as to what discharge from the patient is infectious. The old idea that the desquamation was especially dangerous is not greatly credited by most of those with long experience of the disease, while morbid conditions of the nasopharynx and other parts, especially those causing discharges, are viewed with the most suspicion. There is a growing tendency also to doubt the time-honoured belief that scarlet fever is to any important extent spread by infected articles, a belief sanctioned by the disinfecting operations which are carried out in every case by nearly all local authorities. This practice is much on the same footing as that of the hospital isolation of scarlet fever, and we believe that several medical officers of health have abandoned it, without any increase in the disease becoming apparent in their districts. In our present state of knowledge it is difficult to affirm or deny that infected articles may carry the disease, or to say how long the infection can persist in them. In anthrax and vaccinia we have examples of diseases in which the fomites will retain the infection for prolonged periods. An outbreak of scarlet fever in a home county was recently attributed to the reading of a book which had been used by a scarlatinal case 20 years before. In regard to this and similar instances we should not lose sight of the circumstance that in the investigation of scarlet fever the most careful inquiry often fails to reveal the immediate source of infection.

THE CŒLIAC DISEASE.

ACCORDING to Dr. Rood Taylor,[1] of Minneapolis, who records seven illustrative cases, the cœliac disease was first described by Gee in 1888, since when Reginald Miller [2] has found about 50 papers bearing on the subject, though many of the cases are described by other names, such as Herter's infantilism, intestinal infantilism, acholia, pancreatic infantilism, or chronic intestinal indigestion. The disease has never been recognised in a breast-fed baby. In its typical form it is always chronic. The patients are under size and under weight. X rays show delayed skeletal development, and the muscles are small, soft, and weak. The abdomen is distended, the stools are voluminous, grey, greenish, or brown, sometimes of the consistence of porridge, sometimes full of mucus, and sometimes liquid. Acute attacks of diarrhœa occasionally occur, especially after ingestion of carbohydrates, but most of the time the patient has not more than two or three stools daily. The fat content of the fæces is greatly increased. The discharge of calcium is also increased and to a greater extent than is accounted for by the amount of fatty acid, volatile acid, and phosphate present in the stools. The rate of metabolism is slightly diminished. There is usually some degree of secondary anæmia and the spleen is often moderately enlarged. The mental activity of the patients, as a rule, far outstrips their physical growth. The most frequent complications are scurvy, tetany, œdema, and purpura. In three of the five cases of undoubted cœliac disease on record, in which an autopsy has been prepared, there were small-celled infiltration and fibrosis, especially about the pancreatic ducts, and one also showed fatty degeneration of the liver. In the other two cases no changes could be found which could in any way explain the lesions present. According to some writers, the disease is due to infection either of the bowel contents or of the intestine with bacilli such as *B. bifidus*, *B. infantilis*, or *B. coli*, and a resulting defect in absorption. Other hypotheses include chronic infection with some type of dysentery bacillus, deficient pancreatic secretion, deficient secretion of bile, vitamin deficiency, and an overgrowth of proteolytic bacteria in the bowel contents. In all Dr. Taylor's cases the disease had been preceded by a long period of unsuitable feeding or by a parenteral infection such as whooping-cough or chicken-pox, or both. Gastric achlorhydria was present in the five cases in which the stomach contents were examined. X rays in each case showed an atonic dilated colon. The liver was smaller than normal in every case. One case was complicated by Banti's disease, another case showed leucin and tyrosin in the urine, and in yet another patient the duodenal fluid contained urobilinogen. Dr. Taylor recommends that the following principles should be followed in the dietetic treatment of the disease: (1) The use of sour milk and fruit acids in recognition of the achlorhydria; (2) a supply of readily absorbable carbohydrate primarily for its good effect upon the liver; (3) restriction to a high protein diet for months before adding starches and fats; (4) prevention of fæcal accumulation which may undergo bacterial decomposition.

INDIRECT ADVERTISEMENT.

IN THE LANCET of Dec. 9th, 1922, we published a report of the discussion by the General Medical Council during its November session of the motion brought before it with respect to medical advertising. Various inaccurate statements have recently been made in the lay press in connexion with action said to have been taken by the Council in this direction. We learn, for example, that the Council "have lost no time in taking action upon medical advertising," and that the matter has been submitted to the Executive Committee, the "full text" of whose "decision" is then set out. We are authorised to state that no action of any kind has yet been taken by the Council or by the Executive Committee. We may point out that the "full text" above referred to is a reproduction, not quite in the same words, of the resolution relating to advertising adopted by the Council on Nov. 27th, 1905, portions of which were read by Dr. Bolam in the course of his address to the Council on Nov. 30th last.

A medical contemporary, which has been misled in company with the lay papers, may have been crediting the Council with action in response to a feeling that "something ought to be done," and the following letter to THE LANCET supports the idea. M.D. writes:—

> "In view of the late pronouncement of the General Medical Council on advertising what are we to think of a eulogy contained in the *Western Mail*—it even takes up more space than the actual announcement of the Royal birth—of a well-known physician—of his brother—of his late father—of his mother—of his sister—and capping all by the insertion of his photograph. The occasion is the birth of Master Lascelles, and the Welsh physician's name does not appear in the bulletin, or the *Court Circular*. Are the favoured ones in the medical profession who attend the 'great ones of the earth' exempt from the regulations of the General Medical Council?"

We have read the article sent to us and agree that it is deplorable. We are ready to believe that the doctor in question had nothing to do with its publication, but the material for the réclame seems surely to have been obtained from friends or relatives.

A TUBERCULOSIS CENSUS.

UNDER the heading "An Investigation into the Distribution of Pulmonary Tuberculosis and Other Respiratory Diseases in the West Riding of Yorkshire," Dr. John B. McDougall[1] has recently published a very instructive survey of the incidence of tuberculosis in various districts and under various conditions. The population of the West Riding is just over three million, and the investigations were confined to death-rates and not to dispensary attendances or notifications of phthisis. It was found that pulmonary tuberculosis inflicts a much higher mortality rate on children in and about Rotherham than in Western Yorkshire, and that the mortality rate in adults over 45 is greater in Western Yorkshire than in the Rotherham area. Again, although the mortality rate from phthisis in Bolton-on-Dearne and Wath-on-Dearne is about double that in Todmorden Borough in children and young adults, the position is reversed in adults over the age of 45. These apparent paradoxes are of special interest in connexion with Dr. J. Brownlee's differentiation of pulmonary tuberculosis into age types. Many other interesting points are brought out by Dr. McDougall's survey, which deals with the relation of subsoil, altitude, rainfall, housing conditions, and other factors to the incidence of tuberculosis. He concludes that "infection, immunity, and industrial environment play the most important rôle in determining the incidence of disease in various age groups."

SCHOOL INFECTIONS.

A CODE of rules first issued nearly 40 years ago by the Medical Officers of Schools Association is largely responsible for the remarkable immunity to disease in our public schools. The eighth edition, which has just appeared,[1] deals fully with the newer diseases—cerebro-spinal fever, poliomyelitis, and encephalitis lethargica. The important fact is noted that the diphtheria bacilli harboured by so-called carriers are often found to be avirulent when tested on guinea-pigs, and that such carriers may then be considered innocuous. The virulence test should always be applied. Attention is also drawn to glandular fever, which may occur in epidemic form and be mistaken for mumps. The appendix on disinfection in the new edition is much simplified in the light of recent knowledge. Cleanliness is recommended as the basis of all disinfection, and soap and water as the best general disinfectant, the effect being enhanced by the addition of washing soda to the water. With regard to the food and milk supply, the school medical officer is advised to consider and investigate the dietaries, their balance and composition, in respect of calories, protein content and vitamins, and the variation in meals. It is recommended that the milk supplied to the schools should be of a standard of purity not lower than Grade A, while the contract for supply should always include a proviso that milk can be purchased elsewhere and charged against the contractor if at any time the milk supplied by him is proved on delivery not to be "of the nature, substance, and quality demanded." This up-to-date and well-indexed code should be in the hands of every school medical officer.

AN AUSTRALIAN INSTITUTE OF TROPICAL MEDICINE.

THERE seems to be every prospect of the development of an Australian Institute of Tropical Medicine, which has recently passed through many vicissitudes, into a first-class school. For many years it had been realised that Australia should provide a place where up-to-date training in tropical medicine is given, for part of Australia lies within the tropics and is in intimate contact with countries infected with malaria and many other exotic diseases. The Australian Institute of Tropical Medicine was opened in Townsville, Queensland, in 1913, under the directorship of Anton Breinl, with a highly-trained and competent staff, but the original conception of making the institute a post-graduate school for tropical hygiene failed. At a later date the Federal Government took over control, but, on account of unforeseen but inevitable difficulties in war time, had no better success. The failure of the institute as a school gave the staff admirable opportunities for research work, which has been carried out with success. Dr. Breinl and his colleagues made valuable contributions to the physiology of the white man in the tropics, having a direct bearing upon the "White Australia" Policy. With the creation of the Commonwealth Department of Health the reconstruction of the Australian Institute of Tropical Medicine was undertaken. By arrangement with the International Health Board of the Rockefeller Foundation a section of the work on hookworm prevention is to be undertaken in collaboration with the staff of the institute, and simultaneously an inquiry into the incidence of malaria and filariasis has begun. With the reorganisation of the staff, Dr. R. W. Cilento has been appointed to take charge, and the institute will henceforward be used as one of the laboratories under the Department of Health. The Federal authorities have also arranged with the universities of Melbourne and Sydney for the institution of a course in tropical hygiene requisite for a diploma. The first course commenced with the year, and the programme as now outlined would seem an admirable one. The movement is capable of expansion and deserving of success.

MESENTERIC VASCULAR OCCLUSION.

Dr. Leo Brady,[1] of Baltimore, reviews the literature of mesenteric vascular occlusion and records 14 cases which have occurred at the Johns Hopkins Hospital since 1895, including one in which he successfully resected the infarcted intestine. In 11 cases intestinal infarction occurred, while in 3, in which the condition was not recognised until the autopsy, the thrombosis progressed very slowly and sufficient collateral circulation developed to prevent the formation of an infarction. In all but one case, in which the inferior mesenteric vessels were affected, the occlusion was in the superior mesenteric vessels. Contrary to what has been found by most observers, who state that the veins are affected much less frequently than the arteries, in the present series the mesenteric arteries were involved in only 4 cases and the veins in 8; in 2 it was impossible to tell which of the two had caused the infarction. Occlusion of the mesenteric veins is always due to thrombosis. Either embolism or thrombosis may cause occlusion of the mesenteric arteries. Post mortem, however, it is often difficult to distinguish between thrombosis and embolism of the mesenteric arteries. The average age of the patients in the present series was 45 years, the oldest being 80 and the youngest 24; 8 were men, 6 were women, 11 were white, and 3 coloured. In 10 cases the following ætiological factors were present: endocarditis with aortic insufficiency and stenosis, 2 cases; marked arteriosclerosis, 2 cases; cirrhosis of the liver, 2 cases; Raynaud's disease, 1 case; carcinoma of the pancreas with metastases in the liver and neighbouring glands, 1 case; polycythæmia, 1 case; partially strangulated inguinal hernia with abscess formation, 1 case. In all the cases there was a history of abdominal pain and vomiting, and on examination abdominal tenderness and muscular spasm were found. At the onset the temperature was only slightly raised, but at the end of 24 hours almost every patient had a temperature of at least 102° F. In most cases there was a leucocytosis of 20,000 and a pulse-rate of 120. Constipation was present in all, but in only two instances was blood passed by rectum. The rapidity with which the symptoms developed depended on the size of the mesenteric vessel which was occluded. In the 11 cases of intestinal infarction the duration of symptoms before death or operation ranged from 1 to 23 days. Unlike some writers who hold that there is a clinical picture characteristic of mesenteric vascular occlusion, Dr. Brady maintains that the symptoms are indistinguishable from those of acute intestinal obstruction due to other causes. On laparotomy, which is the only method of treatment for intestinal infarction, the peritoneal cavity is usually found to contain a moderate amount of sero-sanguineous fluid, which in advanced cases is frequently sanguineo-purulent. The mesentery supplying the infarcted intestine is of the same purplish black colour as the intestine down to its root. Eight of the 11 cases of mesenteric vascular occlusion that caused intestinal infarction proved fatal—a mortality of 72·5 per cent.—and 5 of the 8 patients treated by laparotomy died—an operation mortality of 62·5 per cent. High as these mortality rates are, they show a distinct improvement over those of Jackson, Porter, and Quinby, who, in 1904, reported a total mortality of 94 per cent. and an operative mortality of 92 per cent. for all the cases which had been published until then.

INDUSTRIAL MEDICINE.

The science of industrial medicine is gathering way; it now possesses its own journals and its own band of research workers. The human organism is a delicate reagent, and no better way exists of studying its reactions than by close observation made upon groups of workers in this or that industry exposed to some particular influence whether chemical or environmental. New knowledge is being acquired, and reactions are taking place between it and other fundamental sciences. Thus physiology is being affected by studies of human activity in industry; while, on the other hand, the results of physiological research are being given practical application in revolutionising the science of ventilation in factories and are making known the necessity for studying the relation between energy output and food requirements. In another direction research into industrial work associated with exposure to heat and humidity has thrown light on the causation of heat stroke. Two particularly interesting lines of advance which are being followed may be especially noted. The experimental production of cancer in animals has resulted from observing how epitheliomata occurred among those exposed to coal-tar products, such as chimney sweeps and men manipulating pitch; the materials to which they were exposed, when applied over a long period to the tissues of animals, cause malignant growths, the study of which from their commencement is being thereby rendered possible.[1] The discovery of the toxicity of colloidal silica, of its capacity to cause fibrosis in the body, and of its power to break down the resistance of rodents to tuberculosis, originated through noting how those exposed occupationally to the inhalation of silica dust suffered an appalling mortality from phthisis[2]; there are possibilities in this research which may throw important light upon the whole question of tuberculosis. Workers in other fields of medicine who are unable to follow all that is being done require a summary to help them. Such a summary has just been provided in a text-book which we review on p. 339 of our present issue. Although this science originated in this country, its practice is being applied far more in the United States than at home, and applied with economic success. We continue to maintain our position with regard to research, but even here our colleagues in the United States are treading closely upon our heels. Unless our industrial world awakens to what is taking place, America will assuredly reap the harvest, the seed of which we have sown.

THE ROUTINE TREATMENT OF SYPHILIS.

A modification of the routine treatment of syphilis which has been carried out at King's College Hospital is described by Dr. M. Sydney Thomson in the January number of the *British Journal of Dermatology and Syphilis*. The modification consists in the administration of at least three intravenous injections of 0·9 g. of novarsenobillon, with an interval of three weeks between each injection. These doses are continued until the W.R. becomes negative. The object that the writer has in view in carrying out this particular plan of treatment is to avoid complications without in any way impairing the efficiency of the end-results. He places great emphasis on the danger of accumulation of arsenic in the body, and considers that the old method of repeated small doses of novarsenobillon is particularly liable to lead to such accumulation. He also mentions the possibility that the spirochæte may develop a resistance to arsenic under the form of treatment commonly in vogue. Clinical experience has shown that a dose of 0·9 g. novarsenobillon is well tolerated and that the interval of three weeks between successive injections is the right one. Dr. Thomson summarises the results obtained from this form of treatment in his own clinic. Analysing 500 cases subjected to this method, he states that of primary cases 90 per cent. gave a persistently negative W.R. after their third injection, and a further 6·5 per cent. after four to eight injections. Of the secondary cases, 71 per cent. gave a negative W.R. after the third injection and 19 per cent. after four to seven injections. Patients are at the same time placed on mercurial treatment, the mercury being given preferably in the form of pills. He does not favour intramuscular injections as a routine, as he considers the tendency to loculation a very real objection. As a guide to treatment he considers the W.R. of the greatest value, a relapsing W.R. generally giving warning of a clinical relapse. In the case of pregnancy, however, the reaction is much less reliable. No ill-results have followed the adoption of Dr. Thomson's methods in cases of pregnancy, even when injections were continued up to the day of parturition.

THE ACID-BASE EQUILIBRIUM OF THE BLOOD.

The subject of the reaction of the blood, and the acid-base equilibrium on which this depends, is one of considerable importance in many branches of medical research. The theory of the acid-base equilibrium rests on well-ascertained facts, and may, on the whole, be considered to be fully established. The same cannot be said with regard to our knowledge of the alterations in acid-base equilibrium even in health, still less in disease. The relation of alterations of blood reaction to respiration, and vice versa, although the subject of numerous inquiries, cannot be said to have been fully explored. Yet, although there are differences of opinion, we are led to believe, according to the newly-published report on this subject by the Medical Research Council,[1] that these differences of opinion are less fundamental than has often been supposed. They can, as a fact, be traced in part to simple differences in nomenclature and definition, in part also to differences in experimental technique. As an illustration we may mention the nomenclature in regard to acidosis. The Committee responsible for the report suggest that this term should be abandoned[2] altogether, and that the two separate conditions which have hitherto been given this common name should be re-named. For conditions in which the reaction of the *circulating blood* is less alkaline than normal, they propose, where a name is used at all, to employ the term "acidæmia": for the state in which the blood is abnormally alkaline the term "alkalæmia" is proposed. These terms do not refer to the fixed carbon dioxide content of the plasma, nor to the presence or absence of acetone bodies in the blood or urine. When these substances appear, then the name "ketosis" is suggested, quite irrespective of what the reaction of the blood may be. Another instance in which the current nomenclature is criticised is in relation to the term "alkali reserve"; for various reasons this is considered to be unsatisfactory, and the Committee suggest the use of the term "fixed carbon dioxide" as less equivocal. As regards discrepancies attributable to differences of technique, the most striking ones discussed are those for the determination of the carbon dioxide pressure in the blood and alveolar air, and those concerned with the determination of the reaction of the blood in exercise. The report, expressing the considered and agreed statement of 11 members, all of whom have worked on various branches of the subject, should prove very valuable, and provide some solid ground for further progress. The subject is not treated in great detail, the object of the report being merely to present the current opinions held in this country.

"ROYAL OCTAVO."

Mr. S. P. Vivian has lost no time in introducing an innovation into the General Register Office for which all students and librarians will bless him. The first instalment of the Registrar-General's Statistical Review of England and Wales [1] for the year 1921 has just appeared in "royal octavo" instead of "folio foolscap." It is the statutory duty of the Registrar-General to collect and publish in the intervals between one census and another such information as will best help central and local authorities, and in order to do so effectively he has now divided the tables hitherto published together into two sections of (1) medical statistics, (2) civil statistics—each section to be issued when ready without waiting for the other. The present volume consists of those tables, contained in the old index, which had a medical interest, suitably rearranged. It also comprises the annual figures of the notifications of infectious diseases hitherto separately published. We must not wait for a formal review of the volume to say how much the innovation and the handy form are appreciated.

NEW WORK ON RENAL SECRETION.

PHYSIOLOGISTS have long been divided into two camps, those who believe that the excretion of urine can be explained entirely on the basis of filtration and reabsorption, and those who consider that in order to explain it, it is necessary to add to filtration and reabsorption secretion by the tubules. In the current *Bulletin* of the Johns Hopkins Hospital appears an article by E. K. Marshall, jun., and J. L. Vickers, entitled the Mechanism of the Elimination of Phenolsulphonephthalein by the Kidney—a proof of Secretion by the Convoluted Tubules. These investigators have set out to throw light on the difficult subject of renal secretion. In their paper the writers briefly summarise the existing evidence that favours the secretory theory of urinary excretion under the following headings: (1) Investigations by histochemical methods indicating an accumulation of various urinary constituents or foreign substances in the cells of the tubules; (2) the classical experiments of Nussbaum on the amphibian kidney; (3) the finding of various granules and vacuoles in the cells of the convoluted tubules; (4) attempts to determine the site of elimination of various substances by injuring certain parts of the kidneys and noting the effect of this damage on elimination. The experiments performed on dogs by the writers, dealing with the elimination of phenolsulphonephthalein by the kidney, and described in their paper, appear to lend additional support to the view that in urinary excretion there occurs an active secretion as well as a filtration and reabsorption in the kidney. They found that if phenolsulphonephthalein is injected into a dog, the animal is killed shortly afterwards, the distribution of the phthalein in the blood and other tissues of the body being studied, the kidneys will be found to contain an abnormally high concentration of that substance. In order to be sure that elimination of the urine had ceased during the experiment the spinal cord was divided at the atlanto-occipital junction, elimination of the urine ceasing when the blood pressure fell below 40 mm. The concentration of phthalein in the various tissues of the body was then determined, and it was found that on occasions the kidneys contained as much as 35 per cent. of the total amount of phthalein injected, although they made up only about 0·6 per cent. of the total body-weight. The concentration of phthalein in the kidneys was invariably found to be many times greater than the concentration in the blood or any other tissue. As no urine flowed from the ureters during the experiments the phthalein must either have been concentrated in the renal cells or transferred through these to the lumen of the tubules. Evidence strongly points to the former of these two possibilities having occurred. In longitudinal sections of the kidney the phthalein was made evident by a brilliant yellow colour, and it could be easily seen that the yellow colour was almost entirely confined to the cells of the convoluted tubules, and that it was absent from the lumen. It will, therefore, appear that the phthalein had been specifically taken up from the blood by the cells of the convoluted tubules. Presumably after storing in these cells it was slowly given out in the urine.

These interesting experiments are undoubtedly a valuable contribution to the physiology of urinary excretion. They furnish sufficiently strong evidence that the processes which have been designated filtration, reabsorption, and secretion all play a rôle in the elimination of the urine, and that filtration and reabsorption alone cannot account for the phenomenon of urine excretion.

INFECTIOUS MONONUCLEOSIS.

ACCORDING to Dr. Warfield T. Longcope,[1] of the Presbyterian Hospital, New York, who records ten cases which he has observed in the course of the last 13 years, the terms "infectious mononucleosis," "glandular fever," and "acute benign lymphoblastosis" have been applied to a symptom-complex which, though not very common, is sufficiently frequent to be of importance, both from the practical and theoretical standpoint. The clinical course presents a fairly uniform picture. The disease usually occurs in young adults or adolescents. Many of the patients, as is exemplified in Dr. Longcope's series, have been medical students or young physicians. The onset is gradual, with malaise, headache, and irregular fever. Pharyngitis, tonsillitis, or tracheitis may be initial manifestations. Rarely the first sign of the disease is an enlargement of the cervical lymph glands; as a rule, the glands do not become enlarged till a few days later. The enlargement is sometimes confined to the cervical glands, but frequently the axillary, inguinal, epitrochlear, and possibly the bronchial glands become involved. In some cases the spleen becomes enlarged and tender during the first week. By the seventh day the mononucleosis is well marked; it increases until the eighteenth day, when it gradually subsides concurrently with a fall in the temperature and a disappearance of the glandular enlargement. Convalescence is rapid and uneventful. The disease has been mistaken for tuberculosis, typhoid, Hodgkin's disease, and leukæmia, while in a few cases syphilis has been suspected, but there is no evidence that infectious mononucleosis is at all related to any of these diseases. From leukæmia, to which it bears the closest resemblance, it is distinguished by the early and marked enlargement of the lymph glands, the absence of anæmia and purpura, and the histological and biological characteristics of the mononuclear cells, the predominant type of which is somewhat larger than the small lymphocytes and contains oval or reniform nuclei, usually without definite nucleoli. Whether infectious mononucleosis is identical with the glandular fever described by Pfeiffer cannot be decided until epidemics of infectious mononucleosis are reported or until cases of glandular fever are described in which the blood picture differs essentially from that in infectious mononucleosis. Although a few specific infections such as typhoid, pertussis, malaria, Malta fever, and possibly tuberculosis, and intoxications such as those due to arsphenamine and carbon tetrachloride may produce a mononucleosis, the increase in the mononuclear cells in these cases is not very great, and is often insignificant compared with the considerable mononucleosis encountered in the condition under discussion. The ætiological agent is unknown. Although Blaedorn and Houghton, who found spirilla and fusiform bacilli in smears from the tonsils in three of their four cases, are inclined to regard the disease as a form of Vincent's angina, the clinical appearances in the throat do not correspond to the picture of Vincent's angina.

MENTAL HOSPITALS ADMINISTRATION: A NEW MENTAL TREATMENT BILL.

THE recommendations of the Committee on the Administration of Public Mental Hospitals, which were set forth in full in THE LANCET of August 12th, 1922, have been incorporated in a letter addressed to the visiting committees of these hospitals by Sir Frederick Willis, as chairman of the Board of Control. The most encouraging feature of his letter, apart from the cordiality with which the Board endorses the recommendations, is the incidental reference to the provisions of a Mental Treatment Bill which it is proposed to introduce this coming session. Facilities for the early treatment of cases of incipient mental disorder without certification are to be anticipated, and some enabling provision for after-care; it is intended also to include a clause whereby the combination of local authorities for any purpose, such as research or laboratory accommodation, may be regularised, while another clause will legislate for the co-option upon visiting committees of specially qualified persons who are not members of the local council. For the rest, the Board, in detailing the recommendations, have wisely discriminated between those which could be adopted without involving heavy financial commitments, and those for which it is manifestly inopportune to press in these lean years. Nine out of the fifteen recommendations are regarded as in the former class.

The suggestions as to the classification of patients with some regard to former surroundings, as to the posting of notices calling attention to the right of patients to send unopened letters to certain authorities, and the provision of letter-boxes for this purpose, are approved and passed on without comment. The recommendation that the superintendent shall be a medical practitioner, preferably with a diploma in psychological medicine, and not without general hospital experience, is warmly endorsed by the Board, who emphasise, in addition, the importance of insisting on high medical attainments and personal qualities, on organising ability, and on an appreciation of the use of laboratory adjuncts to treatment. Elsewhere in the letter the Board record their opinion that much more extensive use should be made in the ordinary routine of laboratory and other modern methods of diagnosis and treatment. Following a suggestion made, the Board have arranged for a small advisory committee to be at the disposal of any visiting committee who may desire to consult them in regard to the filling of vacant posts, which should be advertised. The appointment of a consultant staff to a mental hospital has the strong approval of the Board, who note with gratification that at most institutions the services, at any rate, of a dental surgeon are already available. With regard to assistant medical officers, the recommendations of the Committee do no more than reiterate the need for increased staff and for the provision of opportunities for study leave, emphasised by the Board in a circular addressed to visiting committees on March 3rd, 1920. In this circular the probable causes of the dearth of suitable applicants for these posts were outlined, the desirability of providing for the more effective treatment upon modern lines of recoverable cases insisted on, and the necessity for affording facilities to raise the standard of training for existing and future medical officers explained. As to the employment of patients, the question of authorising payment to patients doing useful work is under consideration; it is agreed that every endeavour should be made to provide patients with suitable occupation and to arouse their interest. Again, the Board agree that the importance of after-care can scarcely be over-estimated, and suggest that without waiting for the proposed legislation, voluntary effort in this respect should be encouraged—for example, by the formation of local branches of the Mental After-Care Association. The uniformly sympathetic attitude of the Board is well shown by the trivial nature of the only reservation made in forwarding the recommendations. While they agree as to the importance of drawing the attention of friends and relatives of patients to their powers (under Section 79 of the Lunacy Act, 1890) to make application for the discharge of a patient, they consider that this should be done in the rules as to visitation rather than by means of notices in the waiting-rooms as suggested. Arrangements for the visiting of patients by responsible people specially authorised by the local authority, as well as greater facilities for visits from friends and relatives, are also among those alterations which could be effected without much expense and with great advantage to the confidence felt by the public in mental hospital administration. Recommendations affecting the daily comfort of patients, such as the arrangements for daily toilet and the number of hours spent in bed, are specially commended to visiting committees.

As to the suggestions which would involve heavier expenditure, the limitation of the size of hospitals to 1000 beds, and the adoption of the pavilion system of buildings, need not, it is said, arise unless the building of a new institution or the enlargement of an existing one is contemplated. The remaining recommendations in this category deal with the nursing service and the dietary, and are being considered by special committees appointed by the Board of Control; a further communication will embody the results of these deliberations. The Board are giving careful consideration to the revision of the definition of "seclusion," as suggested by the Committee. Sir Frederick Willis's letter concludes with an appreciation of the helpful spirit in which the recommendations of the Committee were drafted. Indeed, most of them cover points which the Board have for some time been pressing upon the notice of local authorities. It is noticeable also how closely they coincide with the demands made at the Conference of Medical Superintendents and Representatives of Local Authorities called together in January, 1922. We commented favourably[1] on these and on the report of the Committee on Administration of Mental Hospitals when they were first issued, and need now add only our conviction that public confidence in the Board of Control will be greatly strengthened by their evident anxiety to use for the advantage of the patients under their care every particle of the present public interest in mental hospital administration.

Sir Charles Ballance will deliver a short appreciation of the Life and Character of the late Mr. Hunter Tod to the members of the Otological Section of the Royal Society of Medicine to-day (Friday) at 5 P.M.

Report 2 of the Industrial Fatigue Research Board, issued[2] to-day, deals with atmospheric conditions in cotton-weaving. It establishes the fact that operatives are exposed to atmospheric conditions which are physiologically unsatisfactory, although it does not dispose of the question whether conditions causing discomfort necessarily result in ill-health.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

VII.

THE TREATMENT OF AURAL DISCHARGE IN CHILDREN.

CHRONIC aural suppuration, a too common condition, which is the direct cause of an immense amount of disability and of a considerable mortality, is nearly all preventable by simple treatment at the early stage of its acute onset, for it is always the result of the persistence of an acute otitis. The public in all ranks of life is sadly in need of education on this matter, and should be taught that an earache, and still more a discharge from the ear, is a sign of serious disease which, if not promptly treated, may result in permanent disability and danger. A woman once brought her baby to my out-patient department because, although it was teething, the ears had failed to discharge, and she thought that something must be wrong with the child to cause this departure from the normal course of events.

The chief causes of chronicity are secondary infection, re-infection, and lack of adequate drainage, and it is on this basis that treatment must be directed. The original source of infection is the entry of micro-organisms along the Eustachian tube from the nasopharynx into the middle ear, and the infection is at first practically always with a single variety of organism; when, however, the tympanum opens through a hole in the membrana into a meatus full of cerumen, epithelial debris, and pus, secondary infection readily takes place, the discharge fails to clear up, and the suppuration becomes chronic. Again, repeated doses of infection may reach the tympanum through the Eustachian tube when the nose or nasopharynx are definitely unhealthy; this appears to be a less important cause of chronicity, for most cases of acute suppuration into a clean meatus will subside, and the drum heal, even though adenoids be present; though in such cases recurrence often recurs at a later date. Further, if there is any lack of free drainage, the bone beneath the very thin mucosa of the tympanum and antrum becomes diseased and the suppuration persists. In the earliest stage, or in mild cases of otitis, the secretion drains through the Eustachian tube; but when it is secreted too rapidly, or when the tube is blocked by inflammatory swelling, it is formed under pressure and earache results; usually the membrane gives way quickly and the pressure is relieved. In all cases of acute otitis media the antrum and mastoid cells participate in the inflammation and the mastoid is commonly tender on pressure during the stage of earache; usually they drain well, when the drum has perforated, and recover, but sometimes a block occurs at the aditus or at the neck of a mastoid cell which keeps up a chronic suppuration, and in rare cases even a mastoid abscess may form although the tympanum recovers and the perforation heals.

Treatment of Acute Suppurative Otitis.

Therefore the principles that should guide us in the treatment of acute suppurative otitis are to combat these factors which make for chronicity. As soon as a child complains of earache, the meatus should be cleared of wax and debris, if necessary by gentle syringing with warm 1 in 60 carbolic lotion, and antiseptic drops instilled every four hours; for this purpose the best drops are carbolic acid 25 gr., glycerine 1 oz., for they possess not only an antiseptic but a decidedly sedative action; the meatus should be filled with this solution, previously warmed, and the affected ear kept uppermost for three minutes; dry heat then should be applied to the side of the head in the form of a rubber hot-water bottle over a large pad of cotton-wool. Incision of the drum is a most valuable measure, which should always be performed early rather than late; it promptly relieves pain and stops the further progress of the disease. The drum should be incised as soon as it is found to be bulging or to present a bright velvety-red appearance, or even when severe earache and fever persist in spite of treatment for 24 hours without improvement. This little operation is quite easy, and is within the power of every practitioner, as it is practically impossible to do harm; a general anæsthetic is most advisable, but gas is sufficient as the mask need not be removed. Afterwards a narrow drain of gauze should be inserted into the meatus and a large pad of wool applied; the latter is changed when wet with the often profuse discharge, while the gauze is changed daily by the doctor; if such personal attention is impossible, the gauze drain may be removed after 24 hours and the carbolic and glycerine drops used. The discharge is at first serous or purulent, but later often becomes mucoid; it should be wiped away with aseptic precautions, but syringing conduces to secondary infection and is inadvisable. The pain should cease in a few hours after free discharge has been established, and the temperature should become normal within two days; if these two symptoms persist without improvement for more than three days, and especially if mastoid tenderness be present or if discharge has ceased, the antrum and mastoid cells must be opened without further delay, unless the perforation has closed, when paracentesis should be repeated. The treatment is the same if the case has not been seen until after rupture of the drum; but owing to the risk of secondary infection from the meatus, the longer the discharge has lasted before treatment, the more likely is it to become chronic. When a child first comes under attention with discharge a week old, with pain, fever, and mastoid tenderness, hot fomentations and three-hourly syringing with hot 1 in 60 carbolic lotion will often bring about a cure.

Two points about acute otitis in young children deserve mention; symptoms pointing to the onset of meningitis may be present, fever to 105°F., rapid pulse, delirium, retraction of the head and strabismus, but such symptoms may quickly disappear after the drum has perforated. Again, in infants especially, but also in children up to the age of 3, there are often no localising symptoms at all; therefore the ears should be examined in every case of unexplained pyrexia in small children. After spontaneous or surgical opening of the drum, the discharge is usually profuse, and may not reach its maximum until the second or third days; after a day or two more it normally then diminishes, and ceases with healing of the drum in two to three weeks. If it continue in greatly diminished quantity and with absence of other symptoms for a maximum of six weeks, it need not give rise to anxiety. But if, at the end of two and a half or three weeks from the onset, free suppuration persists and shows no sign of diminution, even though all other symptoms such as pyrexia, pain, or tenderness have disappeared, it is far wiser to open the antrum and mastoid cells. This operation, the simple antrotomy or Schwartze operation, does not damage the tympanum, on the contrary it may be relied on to produce immediate cessation of discharge with a healthy drum and normal hearing; whereas, if left alone, such a case will almost inevitably remain with a permanent perforation and damaged hearing. The antrotomy wound may be stitched up, with or without a small drain, at the conclusion of the operation, and heals at once. I have been astonished, when operating on such cases, at the quantity of pus found in the mastoid cells.

Treatment at the Chronic Stage.

If the child is brought for treatment when the aural discharge is already chronic, a cure is, of course, far more uncertain; but even here most cases tend to get well if carefully treated, though a permanent perforation often remains, and in such cases discharge frequently recurs. The treatment is on similar lines to those of acute suppuration, careful mopping out of discharge followed by antiseptic drops. It is better to avoid syringing, though this is less dangerous than in acute cases; but it must sometimes be employed when the discharge is very profuse and when the mother cannot be trusted to mop out the meatus properly; I prefer a warm 1–60 carbolic lotion. But even in hospital work most parents can be taught to mop out the ear in a cleanly fashion with cotton-wool on a holder or a matchstick. The most valuable drops in chronic cases consist of boric acid 15 gr., rectified spirit ℥i.; they are sometimes painful at first and may be ordered diluted to half this strength for the early weeks of treatment. Considerable patience is needed and is often rewarded, for I have known ears to heal after two years' continuous treatment. Above all things it is necessary that no water from washing or bathing be allowed to get into the ear; it always makes these cases worse and often starts discharge from a dry quiescent perforation. Small granulations should be touched with a strong solution of nitrate of silver or with trichloracetic acid fused on a probe; larger granulations or polypi must be removed surgically. Rapid recurrence of polypi is an indication for the radical mastoid operation, as also are recurring attacks of earache; I do not propose to discuss at length the indications for operation in chronic otorrhœa, but it may be said that operation is not called for, at any rate in children, merely by persistent discharge, unless it remain very foul or profuse, and that better results are obtained by postponing the radical mastoid operation, when possible, until the child has at least reached his teens.

Unhealthy conditions of the upper air-passages have a most definite influence on otitis media; in children this usually means adenoids and chronic tonsillitis. Adenoids and tonsils should not be removed in the acute stage while there is fever and pain; but when these have subsided and discharge persists to the end of the second week, the removal of a pad of adenoids may cure the otitis and save an operation on the mastoid. All cases of chronic otorrhœa should be examined for adenoids, and these, even if only small, must be removed together with unhealthy tonsils; it is remarkable how often the ear will heal after this operation.

Harold Barwell, M.B. Lond.,
F.R.C.S. Eng.,
Surgeon for Diseases of the Throat and Ear,
St. George's Hospital.

Summary of Previous Articles.

Previous articles in this series have appeared in The Lancet as follows:—

Jan. 13th: II. The Treatment of Early Pulmonary Tuberculosis in the Young Adult, by Dr. Claude Lillingston.

Jan. 20th: III. The Treatment of Neuralgias of the Head and Neck, by Dr. Wilfred Harris.

Jan. 27th: IV. The Treatment of Whooping-Cough, by Dr. T. Izod Bennett.

Feb. 3rd: V. The Treatment of Scabies and Pediculosis, by Dr. H. W. Barber.

Feb. 10th: VI. The Treatment of Abdominal Injuries, by Prof. Charles A. Morton.

Special Articles.

PHYSICALLY DEFECTIVE CHILDREN IN LONDON.

There are some 42 schools for physically defective children under the control of the Education Committee of the London County Council, and in 1920 it was decided that there should be a medical survey of the pupils. Mr. R. C. Elmslie, orthopædic surgeon to St. Bartholomew's Hospital, was invited to undertake it so far as the crippled children were concerned, and his report[1] has just been issued. There were 2891 cripples on the rolls at the time of Mr. Elmslie's inspection and he examined 2294, the remaining 597 being absent for various reasons. One-third of the children were crippled by tuberculosis, affecting principally the spine, hip, or knee-joints. Over two-fifths were crippled by paralysis; of these the majority had suffered from infantile paralysis. One-twelfth had congenital defects, mainly club-foot and dislocation of the hip. The remaining one-fifth had various disabilities, in most cases due to rickets, amputation, or scoliosis. In Mr. Elmslie's opinion no fewer than 28 per cent. of these children required in-patient treatment in orthopædic hospitals. A further 9 per cent., who would be benefited by in-patient treatment, might be sent to a country home instead, provided they could be given out-patient treatment subsequently. Surgical instruments were required by 7 per cent., apart from the children whose appliances were under repair. For 1·6 per cent. permanent residence in an institution would eventually be necessary. For 54 per cent. nothing was required. With regard to tuberculosis, Mr. Elmslie mentions that he had made a similar survey of the crippled children in the L.C.C. schools in 1907, and he remarks on the improved condition of those suffering from tuberculous disease. He says he has little doubt that the improvement in the physical condition of children with tuberculous disease of the spine has resulted largely from the work done at the larger special country hospitals, more particularly the Treloar Hospital at Alton and Queen Mary's Hospital at Carshalton.

Infantile paralysis has now become the most important cause of crippling among children in London. The disease most often arises in infancy, the actual age of onset in 559 cases being as follows:—

Age of onset ..	1	2	3	4	5	6	7	8	9	10
No. of cases ..	211	168	87	50	26	3	7	3	1	3

In making provision for the treatment of this disease, therefore, it is necessary to provide for infants and young children, while almost all cases require the application of suitable splints or mechanical contrivances long before school age, and these may be wanted for many years, even throughout life. The common history of these children is one of years of attendance at an out-patient department, wearing instruments which are constantly broken and under repair, and getting deformities which require repeated admission to hospital for operation. Mr. Elmslie found that of the 758 children suffering from infantile paralysis, 305 required in-patient treatment, and that in 100 cases an instrument was desirable. This did not represent the number of children without appliances but only those who required an instrument which was not actually on order at the time of his visit. In some parts of London, especially in the East End among the patients of the London Hospital, as many as 50 per cent. of the children suffering from infantile paralysis were without their appliances at the time of his visit because they were broken and beyond repair. These children, although without instruments, were not included in the 100 abovementioned. It seems to him, therefore, that the treatment of infantile paralysis in London at the present time is very defective and that a better plan for attacking this, the most serious cause of crippling, is urgently needed. In a general criticism of the treatment of crippling conditions in children Mr. Elmslie expresses some doubt whether the schools for physically defective children are doing as much as they might as centres for the cure of cripples, and thinks the routine examinations should be made by orthopædic surgeons. He thinks also that the coördination of the schools with the local branches of the Invalid Children's Aid Association is not as close as it might be. He believes that expenditure of money on massage, remedial exercises, and electrical work at the schools would not be justified by the results. He thinks that additional accommodation is required for the treatment of tuberculous disease, and particularly of infantile paralysis in special institutions situated outside London. In his opinion it is desirable that any institution which may be organised for crippled children shall be coördinated with the London hospitals, so that children receiving in-patient treatment in the country institution may be transferred to the out-patient department of the appropriate hospital in London. It would be possible, he thinks, to secure such an adequate linking-up if the country hospital were coördinated with four or five of the large general hospitals, as well as with the Royal National Orthopædic Hospital and a few of the more important children's hospitals, and he concludes his report by emphasising the importance of this coördination.

---

[1] London County Council: Education. A Survey of Physically Defective Children. Report of the School Medical Officer, submitting Report by Major R. C. Elmslie. 1923. P. S. King and Son. No. 2201. 9*d.*

Incidentally Mr. Elmslie makes some observations on the admission of tuberculous cases to the special country hospitals. The responsibility for the treatment of tuberculosis in London rests with the County Council, who are required to provide directly or indirectly such facilities for treatment as are necessary. The Council does not maintain institutions of its own for the purpose, but makes use of accommodation provided by other authorities, notably the institutions of the Metropolitan Asylums Board. For the treatment of non-pulmonary tuberculosis in children the Board has reserved a large section of Queen Mary's Hospital at Carshalton with its seaside branch at Littlehampton, as well as Princess Mary's Hospital at Margate, while St. Luke's Hospital, Lowestoft, was opened last year for adults. Mr. Elmslie in his report refers to the fact that many children with tuberculosis of joints are still admitted to Queen Mary's Hospital as Poor-law cases, passing through the infirmaries on the way to the country hospital. He regards this as regrettable because in some cases the parents object to making application through the Poor-law authorities, and in others the children are taken into the infirmaries and kept there for varying periods before being transferred to the country. On the other hand, he finds that a child reaches Carshalton more quickly by application to the Poor-law authorities than to the County Council. He suggests that the reason may be that the number of beds subsidised by the Council is limited, but Sir William Hamer in his introductory note states that no delay can have arisen on this account.

There is a general agreement that it is most desirable that there should be provided for patients with tuberculosis of the spine and the larger joints immediate orthopædic and nursing treatment in hospitals with country surroundings, with workshops capable of supplying the appliances required and with provision for heliotherapy and open-air life. Yet, as was pointed out by Mr. Gordon Pugh, chief medical officer of the Board's surgical tuberculosis service, in a recent address to the Society of Superintendents of Tuberculosis Institutions, there appears not infrequently to be considerable delay in applying for the admission of these patients to the Board's hospitals, and the cases are comparatively few which are received at Queen Mary's Hospital within three months of the disease being recognised. The experience at the Liverpool Country Hospital at Leasowe has been much the same, for during the three years, 1919–21, of 106 cases of spinal tuberculosis completed 55 had been admitted with abscess, sinuses, paraplegia, or marked kyphosis. It is possible that the facilities for treatment provided by the health authorities are not generally realised by surgeons and practitioners, and as a consequence cases of tuberculosis of spine and joints are not always notified at once to the borough medical officers of health with a request for treatment in an appropriate institution. It would undoubtedly be an advantage to the patients and an eventual economy to the taxpayers if such cases were admitted at once and directly into an institution specially equipped to deal with them.

MEDICAL SERVICE IN SCOTLAND, 1914–1919.

THIS record[1] of the Scottish Medical Service Emergency Committee during the war was prepared by Dr. J. R. Currie, a member of the Committee, until recently attached to the Scottish Board of Health, and now Professor of Preventive Medicine at Queen's University, Kingston, Ontario. Sir Alfred Keogh contributes a preface, in which he emphasises the special value of the account to a profession awakened to the important position it should occupy as an authority in State affairs, and pays a tribute to the great public services rendered by Dr. (now Sir) Norman Walker, convener of the Committee, throughout the period of the latter's existence.

Position on the Outbreak of War.

The immediate consequence of the mobilisation of the Forces in August, 1914, was the sudden withdrawal from civil practice in Scotland of about 300 medical men, most of whom held commissions in the Royal Naval Reserve or in the Royal Army Medical Corps, Special Reserve and Territorial Force, or in combatant units. The demands of the Admiralty and War Office for the temporary services of civilian medical practitioners were eagerly met by many younger men not yet in settled practice, so that the customary source for filling vacancies was almost completely cut off. In towns and populous areas many ex tempore arrangements were made, but a number of country areas lost their only doctors, and their need became urgent.

Formation of the Emergency Committee.

Dr. J. R. Hamilton, then chairman of the Scottish Committee of the British Medical Association, called a conference of members of the medical profession in Scotland to consider steps to relieve the situation; the conference met on August 12th, and appointed the Scottish Medical Emergency Committee "for the purpose of assisting to meet the immediate difficulties in regard to medical practice among the civilian population which have arisen or may arise owing to the departure of practitioners summoned to take up military duty." The Committee was composed, at its inauguration, of 15 medical men, seven of whom were appointed ex officio, while eight were elected by the conference. The seven ex officio members were the Presidents of the Royal College of Physicians and of the Royal College of Surgeons, Edinburgh, the President of the Royal Faculty of Physicians and Surgeons, Glasgow, and the Deans of the Faculties of Medicine of the Universities of St. Andrews, Glasgow, Aberdeen, and Edinburgh. Of the eight elected members, six were engaged in general practice; of these, five—Drs. John Adams, G. C. Anderson, John Gordon, J. R. Hamilton, and John Stevens—were office-bearers of the British Medical Association, and the sixth, Dr. John Playfair, was President of the Medical Guild. The two other elected members were Dr. John C. McVail, deputy chairman of the Scottish Insurance Commission, and Dr. Norman Walker, Direct Representative for Scotland on the General Medical Council, and convener of the Committee. At its first meeting the Committee co-opted Dr. J. R. Currie, a medical officer of the Scottish Insurance Commission. The secretary of the Committee was Mr. T. H. Graham, librarian of the Royal College of Physicians, Edinburgh. The headquarters of the Committee were at the Royal College, and its field of enterprise covered the whole of Scotland. The Committee adhered to the 1911 Census as the standard for its calculations up to June, 1916; the population of Scotland, according to that Census, was 4,760,904, and the numerical summary of the profession published in the Directory gave 4032 as the number of practitioners resident in Scotland. A grouping of medical men according to their work gave the following figures: of a total of 3822 Scottish civilian practitioners on August 1st, 1914, there were 376 private practitioners, 1796 insurance practitioners, 248 consultants, 514 whole-time officials, 269 dental and retired practitioners, and 619 unestablished practitioners.

[1] The Mustering of Medical Service in Scotland, 1914–1919. By J. R. Currie; with Preface by Lieut.-General Sir Alfred Keogh, late Director-General of Army Medical Services. Copies may be obtained, post-free, on application to T. H. Graham, Librarian, Royal College of Physicians, Edinburgh. Price 3*s.* paper, 4*s.* 6*d.* cloth.

Early Work of Committee in Civil Sphere.

The early phase of the Committee's work was in the civil sphere, mainly relating to the filling of vacated general practices, with a view to maintaining the efficiency of medical practice so far as was compatible with the requirements of the army, and to safeguarding the interests of practitioners absent on military service. The maintenance of medical practice was the theme of the Committee's first memorandum to the medical profession, published in the Scottish press on August 19th, 1914. A number of spontaneous local undertakings by members of the British medical profession marked the early days of the war; these related to attendance on the patients of practitioners called away on active service—emergency medical bureaus being established at Dundee and other places—and to gratuitous medical attendance in Great Britain to the dependents of men on service, in coöperation with local relief committees and others. In Scotland, by the end of 1914, the Emergency Committee had overcome the most pressing difficulties with regard to single-handed areas; for instance, the army authorities, to whom representations had been made concerning territorial medical officers, issued in December instructions relating to exchange, substitution, or temporary demobilisation of such officers when a mobilised territorial unit was moved from its own locality, to enable the medical officer to remain at home, if necessary, in charge of his civil work. Reviewing the medical situation in Scotland at the end of that year, the Committee ascertained that of 1796 insurance practitioners, 162 were on active service; information with regard to other practitioners was less precise, but it was clear that a material shrinkage of numbers had taken place affecting all classes of practitioners engaged in active work. Faithful attention had been paid to the Committee's advice with regard to the cutting down of resident staffs of large hospitals and infirmaries.

Prevention of Indiscriminate Depletion of Medical Personnel.

In January, 1915, the Committee issued its second memorandum, dealing more particularly with the home interests of practitioners serving with His Majesty's Forces. In the same month the Council of the British Medical Association appointed a special committee to take such action in England, corresponding with that of the Emergency Committee in Scotland, as might seem advisable. Friendly relations were maintained throughout the war between the Emergency Committee and its English co-workers. In March the Director-General of Army Medical Services explained, in a letter addressed to the medical press, the position with regard to the employment of medical men for the army, and claimed the support and service of the medical profession. The Committee thereupon issued their third memorandum, calling the attention of the public to the great strain devolving upon many medical practitioners, proposing to educational authorities that some of their medical officers should be wholly or partially released in order to resume general medical work, and urging retired doctors and those on holiday from the medical schools to lighten the burden of country practitioners. Meanwhile, individual applications for commissions by medical men had increased as a result of the Director-General's letter. To prevent indiscriminate depletion of medical personnel, the Committee joined in an agreement with the War Office and the Scottish Insurance Commission, by which all names of Scottish medical applicants for military service were referred to the Commission, who conferred with the Committee and intimated to the War Office their approval of or objection to the applicant's employment with the army.

The Committee as a Recognised Recruiting Agency.

Later in the year the Committee was recognised by the War Office as a recruiting agency; the Insurance Commission withdrew, and the committee negotiated directly with the War Office. In April the special committee of the British Medical Association urged all divisions to devise means to free medical men willing to apply for commissions, and to make arrangements with local military authorities for part-time work with troops by civil practitioners. The measures proposed were promptly acted upon in Scotland. In May, at a second representative conference of the Scottish medical profession, it was resolved to provide before July at least 400 additional medical men for the army, and the Scottish Committee of the B.M.A. informed branches of the Association as to the quota expected from them; but in order that this activity might not seem to run counter to the purposes of the Emergency Committee the two bodies now conferred, and the Emergency Committee was entrusted with the records of the Scottish Committee, and with the duty of coördinating and organising the provision of medical officers for the army. The Committee therefore accepted the control of medical recruiting in Scotland with the approval of the War Office and the support of the B.M.A. Its main endeavour was the provision of temporary medical officers for the regular army; no general agreement with the navy or with the territorial force was made. The Committee adopted as its local administrative areas the divisions of the B.M.A., the four Glasgow divisions being counted as one. A general inquiry in May, 1915, showed that the ratio of population per general practitioner had risen since August 1st, 1914, from 2192 to 2576. In June, 1915, the Committee issued a fourth memorandum relating to the scheme for rapidly supplying 380 (reduced from 400) medical men to the army. One hundred were expected from among the graduates of July; this left 280 practitioners, who were summoned in three "calls," the final one in October. Certain rumours arose during this time attributing exaggeration of army demands, but these were quieted by a statement of the Committee giving the facts. The total output of medical men was 347 in lieu of the 380 asked for, the supply being close up to the actual demand.

The Committee under Lord Derby's Scheme.

At the end of 1915 the Emergency Committee became a recruiting authority in Lord Derby's scheme, with a status equivalent to that of a local recruiting committee, a field extending throughout Scotland, and a duty to canvass all medical men of military age within that field. The Committee was itself regarded as a tribunal for medical purposes, and at this period Prof. Robert Muir, professor of pathology, and Prof. T. K. Monro, Regius professor of the practice of medicine, both of the University of Glasgow, were coöpted to membership. The Committee proceeded to compile a medical war register of Scotland. The total number of medical men on service had risen from 641 on May 15th to 1290 at the end of 1915. That is to say, one-third of the medical personnel of Scotland was by this time on service.

Supervention of the Military Service Act, 1916.

The 1916 recruiting scheme, announced in the Committee's sixth memorandum (December, 1915), came into effect on Jan. 1st and continued in being for about six months. The passing of the Military Service Act of the year modified the later stages of its working for practitioners of military age. Central control and local consultation were the principles of the scheme; 75 per cent. of the Scottish medical profession had returned forms under the scheme, offering whole-time or part-time service; a seventh memorandum pressing those who had not already replied to do so was productive of results. In March the Committee warned local war committees of a general call of 100 Scottish practitioners; the pace of supply was slower than heretofore as the means of filling vacancies became more difficult. The Military Service Act, 1916, took effect on March 2nd; medical men were exempt from the normal operations of the lay recruiting authorities under Lord Derby's scheme, and various other provisions had been made in recognition of the peculiar position of the profession, but at the end of February all medical men under the age of 41 were directed to attest. By Army Council Instruction No. 485 (March 3rd), the Committee's war register was assigned a definite function in the scheme of compulsory service, being recognised as a means of dividing practitioners into two classes: the registered, who were destined to remain in reserve until selected for a commission by the R.A.M.C.; and the unregistered, who were liable to be posted to units as laymen. The medical feature of the Military Service Act, 1916 (2), was its seventh section, which provided that claims for exemption by medical men should be dealt with by committees of medical men—a concession marking the special position of the profession.

On June 24th, on the termination of the Committee's 1916 scheme, its powers as Central Professional Committee for Scotland came into full operation. The statutory charge was superimposed on the voluntary recruiting still to be carried on, so that the Committee now had a dual function. Every practitioner who could be freed from civil work was to be so freed, and any practitioner returning from military duty was, if possible, to be replaced by a colleague from his district. Medical practitioners fell into three categories under the committee's range of duties: (*a*) Registered men under 41, (*b*) unregistered men under 41, (*c*) men over 41. Forty-seven claims for exemption were heard by the Committee before the close of the year; of these claims 22 were refused. In November the War Office urgently demanded as large a draft of medical officers as possible. Ninety-two medical men were immediately supplied. Up to the end of 1916, it may be said, 1800 Scottish medical men had taken service with the Forces of the Crown.

The Committee under the Ministry of National Service.

A conference, summoned by the Director-General of the newly-constituted Ministry of National Service, at St. Ermin's, Westminster, which met during March, 1917, recommended as follows: Compulsory medical service for members of the profession, independent of any general application of compulsion to the civil population; provision for remuneration of practitioners transferred by direction of a central executive, but not by payment of State salaries; central executives for England and Wales and for Scotland, and local organisation for purposes of professional mobilisation; appointment of a small medical service advisory board for Great Britain, representative of the central executives, for purposes of consultation with the Director-General of National Service or his deputy. The Government did not see its way to lay a special service on a selected group, however, although independent mobilisation of the medical profession would have received the effective support of the great majority of Scottish practitioners. Such a complete mobilisation was never carried out. In April, following the loss by enemy action of several hospital ships, the necessity for establishment of large hospitals overseas led to the calling up of all medical practitioners of military age. The Committee, anxiously observing the confusion threatened by this measure, disclaimed future responsibility for maintaining the general standard of civilian medical attendance. The Director-General informed the convener of the Committee that the army required 900 additional medical officers, and the Committee undertook to raise 200 officers in ten weeks' time; thereupon the general calling-up order was cancelled. At the end of 1917 the medical department of the Ministry of National Service became intermediary between the War Office and the Emergency Committee. National Service medical boards were instituted, their civilian members working part time in order to prevent complete withdrawal of any practitioner from his normal work. In December the Ministry of National Service circularised Scottish practitioners named by the Emergency Committee, calling upon all medical men who had resigned, or might resign, temporary commissions to resume the latter on expiry. Of 107 claims for exemption during 1917, 51 were not admitted. Meanwhile, certain changes had taken place in the personnel of the committee. Dr. A. D. R. Thomson, of Musselburgh, was appointed to the vacancy created by the death of Dr. J. R. Hamilton; Dr. Laura S. Sandeman, President of the Scottish Association of Medical Women, was coöpted to membership; Mr. J. W. B. (now Sir James) Hodsdon, President of the Royal College of Surgeons, Edinburgh, was also coöpted on the expiry of his ex-officio membership. At the end of the year the convener, Dr. Norman Walker, tendered his resignation of the chairmanship of the Central Professional Committee (to which Mr. Hodsdon was then elected) on account of his tenure of the appointment of Commissioner of Medical Services for the Region of Scotland.

Extended Age and Vocational Control: Special Position of Medical Profession.

The Military Service (Professional Committees Regulations) Order, 1918, placed the appointment of a Central Professional Committee for Scotland under the approval of the Minister of National Service; the medical profession was disjoined from the general body of citizens by a proviso of the Military Service (No. 2) Act, 1918, by which the medical military age was fixed as up to and including 55, as contrasted with 50 for men generally. This Order was superseded by the Military Service (Medical Practitioners) Regulations, 1918, which prescribed that there should be a special medical tribunal for Scotland for dealing with exemptions. The Emergency Committee was constituted as the tribunal, the convener being appointed chairman and continuing to hold his office of Scottish Commissioner of Medical Services. Thus the year 1918 saw two new claims on the medical profession—service up to 55 years of age and vocational control. Approved civilian service included, and was for most purposes equivalent to, substitutionary medical practice undertaken in order to liberate young practitioners otherwise indispensable. The Committee was of the opinion that the posting of medical men to the ranks, as a penal measure after non-compliance with regulations, might in some cases be warranted, but was inadvisable in the public interest. The first step in the Committee's 1918 scheme was the medical examination and grading of medical practitioners under the 1918 Act. A reserve of 45 men was created, available to render public service when requested. The 1918 scheme, however, was cut short by the general cessation of hostilities.

The Armistice: Demobilisation.

The new war register of the Emergency Committee showed that when the Armistice was granted to Germany 2439 Scottish civilian practitioners were serving or had served in the Navy, Army, or Air Force. The total number of civilian practitioners medically domiciled in Scotland on that register was 4281. Before the end of 1918 the committee forwarded the names of 188 practitioners to the Ministry of National Service, who, it was desired, should be released from military service on public grounds—chiefly owing to the influenza epidemic then prevalent in Scotland. A temporary check in demobilisation of medical men resulted from the great destitution in the recently occupied territories of France and Belgium, but progress had been made by the end of the year. At the end of March, 1919, the Ministry of National Service came to an end, and the Committee resumed direct touch with the naval and military authorities. Near the end of May, 403 practitioners had been released, and 594 had been nominated for release, 191 remaining outstanding. From June onwards the Committee concentrated on cases qualified for release by long service or personal hardship. In November the Assistant Director-General of Army Medical Services informed them that a roster of all names of medical officers had been compiled for purposes of release by general officers commanding expeditionary forces and commands, and that no further orders regarding the release of individuals could be issued from the War Office, although cases of extreme hardship might be brought before the general officer commanding-in-chief. By December, 1919, the number of Scottish practitioners remaining in the army was unsubstantial. Future releases were to conform strictly to military procedure, and the Emergency Committee, having no further service to render, dissolved on the 31st of that month.

The above summary of the contents of Dr. Currie's compilation, while necessarily short, makes it clear that among the medical profession in Scotland tne voluntary principle may be said to have survived in substance until the Armistice. Dr. Currie justly claims that the work of the Emergency Committee, which derived its sanction solely from the tacit or expressed approval of the profession, gave evidence of the confidence reposed in the profession by the general public, which must be presumed to have believed that no lay body could exact more from the profession in war-time than the profession was prepared to exact from itself. The volume contains many illustrative tables; the tabular records up to 1916 are derived from contemporary counts employed or made by the committee for recruiting purposes. Of the remaining tables most are based on an examination of the committee's new war register, prepared by the committee in 1918, for its recruiting scheme of that year, and employed after the Armistice in connexion with demobilisation. From Table XIV. we learn that of the 362 deaths of Scottish civilian practitioners from August 2nd, 1914, were as follows: service deaths, 133 up to Dec. 31st, 1919; civil deaths, 229 up to Nov. 11th, 1918. As Sir Alfred Keogh states in his preface, the record of the earlier years of the committee's work, when the Scottish organisation was founded upon a purely voluntary basis, reflects even more distinction upon the medical profession in Scotland than the subsequent or "official" period; and the part played by Scottish medicine in the war is worthy of careful study, if only because of the lessons to be learned from it. "Those of us," he writes, "who have served in the Royal Army Medical Corps and have grown accustomed to the struggle for medical autonomy in relation to military affairs, may conclude from the course of certain transactions recorded in these pages that a not dissimilar movement may one day be believed to be possible in civil medicine. There can be no better example of how much administrative ability and business capacity are locked up in the profession of medicine than the history of its voluntary work in Scotland."

Public Health Services.

THE CONSOLIDATION OF PUBLIC HEALTH ACTS.

Two years ago an Education Act was passed which superseded all the complicated and overlapping education statutes of the past half-century. The result was a well-arranged code containing in a single document the whole law of school attendance, employment of children, and school maintenance and management; in fact everything that parents and magistrates and educational administrators want to know. When will the same simplifying process be applied to our public health law? The Acts are not less numerous and not less complicated; they too, as the Education Acts did, go back for half a century. It would be a great boon to hard-worked medical officers and to those citizens who interest themselves in public health administration, if there were only one Act to handle and understand, and if that Act contained a logically arranged statement in place of the present scattered collection of amending, extending, and overlapping enactments.

Experts in the science of law-making have declared that sequences of statutes like the Public Health Acts or the Housing Acts should be consolidated into a single Act every ten years. If we ask them why this ideal is never attained, we are referred for answer to various frailties of mankind. The politician, it seems, takes no interest in consolidating Acts because they catch no votes. They are unpopular, it appears, with text-book writers and legal practitioners who have mastered the confusion of the existing law and thereout suck no small advantage. The average Member of Parliament, it is said, will sometimes tolerate a consolidating Act if he is assured on good authority that it contains no new law and if he is in a hurry to get home to bed; but more often he wants to distinguish himself by inserting improvements of his own and by introducing controversial amendments which result in wrecking the whole measure. As an instance of this tendency we may refer to Lord Birkenhead's proposals to consolidate the Judicature Acts and thus to bring into the compass of one methodically framed Act the whole law of the constitution and procedure of the High Court of England. The Probate, Divorce, and Admiralty Court, it seems, will have to be omitted from its place in the scheme because enthusiasts would never be able to resist the temptation to bring up the whole question of divorce law reform, which would destroy all chance of the measure passing into law.

Would the same danger attend an attempt to consolidate the law of public health? Health as a general topic is highly attractive to faddists, and it is certainly true that our existing Public Health Acts are susceptible of improvement. As we lately observed, progressive town councils have to spend the rate-payers' money in obtaining various public health powers which ought to be given to all local authorities by the law of the land. The House of Commons has a Select Committee on local legislation. Year after year this Committee recommends that the provisions which are common to so many Local Acts should be inserted in a general Public Health Act. The Committee's report for 1921 gave a list of them. They included clauses for the closing of Sunday schools during epidemics, the cleansing of filthy premises and verminous persons and houses, sanitary restrictions on the sale and storage of food, ice-cream regulations, the provision of street orderly bins, and the removal of tuberculous patients to hospital. Besides urging that these provisions ought to be in a Public Health Act instead of in Local Acts, this Committee has repeatedly recommended the course for which we are now contending—namely, the consolidation of the Public Health Acts of 1875 to 1907. To obtain the ideal code of public health law the best way would be to have two new Acts. The first should be a short amending Act to give the whole country the benefit of the latest approved developments in Local Acts. When that preliminary measure is safely passed, it should be followed immediately by a consolidating Act which would reduce the whole of the then existing public health law into one clearly expressed and properly arranged document. It may be hoped that the Minister of Health will give this matter his earnest attention.

"SCANDAL OF PANEL TREATMENT."

Under this emphatic heading a daily journal asks readers "who have grievances or who know of hard cases" to communicate with them—and we agree that this might be to the good if sufficient space is given to answers and corrections where grievances are found to be based on false foundations. Such a publicity campaign would clear the air. But the journal opens with certain misapprehensions. The statement: "Many doctors have treated panel patients very badly and very differently from the way in which they have treated their private patients," is supported by the allegation that "in London alone 400,000 people who are entitled to free medical attendance have refused to choose a panel doctor, and prefer to pay for medical attendance as private patients." We have no hesitation in challenging this statement, and we wonder where the writer has got his figures. Perhaps he refers to the insured persons who are allowed to make their "own arrangements"—but there were only 2300 of these in London when the count was taken on Oct. 1st, 1922. It may be that the writer has taken his figures from the count of the index and medical registers of the London Insurance Committee given in the agenda of a recent meeting. Now it is well known that the excess of the index register over the medical register is largely due to "inflation" in the course of registration, this inflation being caused by double entries on admission to insurance and delayed deletions on their "ceasing to be insured." Anyone cognisant with the registration system knows that this inflation does not represent living persons. The census figures show that there could not be such a number as two million insured persons in the London county area. The insured population, which is usually about one-third of the total, could scarcely be more than 1½ millions. The statement, therefore, is based upon a gross error.

It may be admitted, however, that a certain number of insured persons do go to private practitioners and pay fees. This is due, on the one hand, to the fact that in London there exist a certain number of non-panel doctors who, being hostile to the Act, persuade patients that they get better treatment by attendance as private patients; and, on the other hand, to the idiosyncrasies of the patients themselves. Many insured persons cannot be disabused of their conviction that they get better medicines from the doctor, and hence are unwilling to go to panel chemists to have their prescriptions dispensed. We hope our contemporary will collect some authentic instances of "scandal"; they would then be fearlessly examined by insurance committees and their medical service subcommittees. For it is evident that any practitioner who is shirking his responsibilities is thereby taking unfair advantage of his colleagues and should be brought to task for it. Our contemporary indicates a recent case where this was done and the doctor fined. It then goes on to quote a statement by Sir Kingsley Wood that the volume of complaint concerning the present service is increasing. No one knows better than he that there is a tribunal for dealing with these complaints, and his help would be valued if he would set himself to explain how the questions can be dealt with by insurance committees. The difficulty of the lock-up surgery in slum areas, for instance, can be remedied by energetic action on the part of insurance committees. Improvement cannot be obtained by mere tightening up of regulations. Definite complaints must be made and the sinners convicted and brought to repentance.

Correspondence.

"Audi alteram partem."

TRACHOMA IN THE NEAR EAST.

To the Editor of THE LANCET.

SIR,—I have seen the annotation in THE LANCET of Oct. 7th, 1922, with this title. As I have trained some of the medical officers and staff for the Palestine Government I thought it well to write to my friend, Colonel G. W. Heron, A.M.S., Director of Health, Palestine Government, on a point in his excellent annual report for 1921, with which I am not in agreement. I wrote as follows:—

> "There is one point in your report, mentioned in THE LANCET for Oct. 7th, p. 773, and having reference to the causation of blindness by trachoma, from which I dissent. On p. 60 of your report you say, 'It accounts for the majority of the cases of blindness so common in this country.' A careful examination of the history in nearly every case of blindness the result of conjunctival disease will show that the deciding factor has been the superimposition on the trachoma of an acute or a chronic attack of bacterial conjunctivitis, due to the gonococcus, or the Koch-Weeks bacillus. This may perhaps sound to you to be an unimportant detail, but I teach that until this is fully understood a real comprehension of trachoma cannot be obtained. I do not deny that trachoma may in certain ways be a cause of blindness (see 'Trachoma and Its Complications in Egypt,' p. 62), but it is not proportionately very common."

Colonel Heron has since written to me expressing his complete agreement with my observation above.

I have read the report of the Trachoma Clinic conducted at Pelham, Georgia, U.S.A. This seems to me the earnest effort of a not very scientific practitioner. It is a pity that he did not study the article on trachoma in the "American Encyclopedia of Ophthalmology" before he wrote his report. I have also seen the article which you published in your issue of Sept. 30th, 1922, by Ticho and Kligler of the Zionist organisation, and Ticho's methods of diagnosis do not appear to be very comprehensive.

In a trachomatous country no case can be pronounced to be free from infection until the cornea has been examined by focal illumination and a good Zeiss loupe of 10 magnification, which shows the vessels of trachomatous pannus running into the clear cornea. Ticho does not mention this in his scanty enumeration of the diagnostic signs of trachoma. What an acute papilla is I have no idea, but the statement that "gonococcal infections when mixed with trachoma protect the eyes from blindness by the appearance of acute pannus" is unsound. The origin of the statement is, I suppose, that I have written about the action of vascularisation of the cornea in protecting the epithelium during the course of an acute conjunctivitis; I am not aware that anyone else has done so. The director of the Medical Service of the Zionist organisation is in regular receipt of my annual reports.

Kligler's statement that there is no increase of trachoma during the summer epidemics of acute conjunctivitis is contrary to experience in a trachomatous country. The most common way in which trachoma is transmitted is by the occurrence of an acute conjunctivitis the result of the transference of contagious material from a trachomatous subject who has been attacked by a Koch-Weeks infection. Then after a varying period, which may be extended to some months, it is found that trachomatous granulations are present.

As regards the question of diet, I was asked by the Rockefeller (International Health) Commission to treat cases of acute conjunctival disease by dietary methods only. I entirely refused to do this, as we have methods of treating the condition which, when properly applied in the out-patient departments, reduce the danger of ulceration to very small proportions, where treatment is commenced before the epithelium is damaged. As regards the influence of diet on trachoma, it is well known that trachoma attacks the conjunctiva of the children of the better-fed classes with as great readiness as the conjunctiva of the children of the starved classes, when the contagious material is present in the conjunctival sac of the mother or of the nurse; bearing in mind, of course, that every kind of infection is thrown off less readily by a badly nourished than a well-nourished organism.

I am, Sir, yours faithfully,
A. F. MACCALLAN.
Department of Public Health, Cairo, Jan. 29th, 1923.

MECHANICAL TREATMENT OF SEVERE DROPSY.

To the Editor of THE LANCET.

SIR,—With reference to a note on this subject by Dr. J. Walter Carr and your editorial note thereon, appearing in THE LANCET of Dec. 2nd, 1922, I wish to take this opportunity of putting on record the following:—

I have been carrying out the simple method of drainage described in the note for over four years now. Having realised the risks that patients run of getting Southey's tubes introduced into their tissues or long incisions made, I hit upon the simple plan of puncturing with a straight surgical needle, and have had resort to the procedure on many an occasion. I have made punctures in subjects suffering from various diseases, such as heart disease, acute nephritis, deficiency œdema, œdema due to extreme secondary anæmia, &c. In fact, it is obvious that the method can be resorted to in all cases where indications for drainage of fluid from tissues exist. Of course, the usual measures should always be given a fair trial, and when swelling does not decrease in a reasonable period of time punctures should be made. The danger of allowing dropsical accumulations to go on increasing must be evident to all clinicians, and failure to produce any impression on such accumulations by the usual therapeutic measures is, I am sure, also within the experience of most. Under such circumstances it is clear we should have resort to some mechanical measures.

I quite agree with Dr. Carr with regard to his experience of "papers of candidates," and also agree with him in his opinion that "the simplest and most effective method of treating severe dropsy . . . is not taught or practised to any large extent." But the reason for these is not far to seek. There is no mention made of such a method in any of the text-books on medicine! There are probably many who like myself practise the method, but so far it has not been put on record. Now that Dr. Carr has written his note, it may be expected that this simple measure of treatment would receive the publicity it so richly deserves, if not even find a place in the future editions of text-books on medicine. Personally I have always felt that the method was so simple and so trivial that in all likelihood it was used by many medical men, and that in any case it did not deserve to be raised to the dignity of being published in any well-known medical journal. But there is really nothing too trivial or too simple from the point of view of bringing benefit to the patient, and I can safely assert that in cases in which I have resorted to it it has really proved to be a life-saving measure.

The technique described by Dr. Carr is just exactly what I also follow except in one minor particular. He makes punctures only over the feet, but it has been my practice not to limit these to the feet only, but also puncture the legs, the thighs, the scrotum in men, and even the lateral aspects of the abdominal wall. These regions are also œdematous in most cases, and punctures over them help to drain the fluid quicker. There is certainly no element of risk in including other regions in the operation than only the feet. The amount of fluid that drains away is sometimes enormous, and in one case of cardiac failure due to mitral stenosis, which was under my care during July, 1921, as much as 20 pints could actually be collected and measured! We may take it that at least half this quantity soaked through the dressing, &c., and could not be collected. What strikes me as a most noteworthy feature about this therapeutic measure is the rapidity with which patients improve once fluid begins to drain away. From a hopelessly water-logged condition and a state of alarmingly increasing dyspnœa, the patient is brought into a state of comparative comfort and safety within such a short time as 24 to 48 hours, and ever after the course to relief and sometimes to cure is smooth and uninterrupted. Not only do drugs begin to act as noted by Dr. Carr, but the kidneys, which up to the time of punctures absolutely refused to eliminate fluid, begin to excrete enormous quantities of urine day after day till the whole anasarca disappears. By adopting this measure we appear to effect a breach at the right spot in the vicious circle in the grip of which the patient is so helpless. It seems undoubted that, left to itself, the termination of such a circle, in almost every case, can only be in death.—I am, Sir, yours faithfully,

B. SANJIVA RAO,
Physician, Government Royapuram Hospital, and
Lecturer in Medicine, Royapuram Medical
School.
Madras, Jan. 10th, 1923.

THE ACTION OF VACCINES.

To the Editor of THE LANCET.

SIR,—I am indebted to Dr. David Thomson for his concise summary, in your issue of Nov. 18th, 1922, of the data on which is founded his belief in the advantages of the method of preparing vaccines named by him the "detoxication" process. But these data do not answer the query in my letter of Nov. 4th. In the matter under discussion we are *not* concerned (1) with the question as to whether "detoxicated" vaccine is superior to ordinary vaccine; (2) or with investigations of a general nature into the chemistry of proteins; (3) or with the alleged advantage of large doses over small doses of antigen in producing the formation of antibody. I am obliged to conclude that Dr. Thomson is unable to bring forward conclusive evidence in refutation of the statement that the "detoxication" process enormously weakens the antigenic value of vaccine.

In my article of Oct. 7th frequent reference was made to the anaphylactic nature of the local, focal, and general reactions following the administration of *minute* doses of vaccine. These reactions, which I have closely studied for some years, are highly specific and are elicited only by the actual antigenic substances in the vaccine. The exhibition of a large dose of antigen in an anaphylactic patient produces serious and even dangerous local, focal, and general reactions. I have used the "anaphylactic test" (as I have named it) as a means of measuring the antigenic value of vaccine, and I regard Dr. Thomson's admission of the absence of severe reactions or harmful effects following the administration of enormous doses of "detoxicated" vaccine as satisfactory proof that the antigenic value of the original vaccine has been enormously reduced by the process of preparation.

I have refrained from criticism of the data on which Dr. Thomson relies in order not to obscure the one point at issue by general discussion.

I am, Sir, yours faithfully,
J. PRATT-JOHNSON.

*** We have referred Dr. J. Pratt-Johnson's letter to Dr. D. Thomson, who replies as follows: "The antigenic value of detoxicated vaccines has been proved by well-recognised and laborious immunity tests in the laboratory. They have also stood the test clinically. Dr. Pratt-Johnson has at last made it clear how he arrived at the conclusion that the detoxicated process weakened the antigenic power of a vaccine at least one hundred times. I had wondered if he had arrived at this opinion after a series of recognised accurate tests, but now it is evident that he has come to his conclusion with extraordinary facility. He has developed in his imagination a new law of immunity—viz., that antigenic efficiency is directly proportional to the reaction produced, and he considers that the reaction is an anaphylactic phenomenon. The detoxication process renders vaccines at least one hundred times less toxic, therefore according to Dr. Pratt-Johnson's new law a simple arithmetical calculation shows that they are at least one hundred times less antigenic. I venture to believe, however, that the laws of immunity and anaphylaxis are not quite so simple as that."—ED. L.

THE LATE DR. J. W. BALLANTYNE AND ANTENATAL WORK.

To the Editor of THE LANCET.

SIR,—I am glad to see that in the obituary notice of Dr. J. W. Ballantyne in THE LANCET of Feb. 3rd attention was called to his efforts for the promotion of antenatal work. For many years Dr. Ballantyne was crying in the wilderness. But his confidence was justified and his pioneer work became an accomplished fact. He began by holding one weekly clinic, but at the time of his death four well-attended clinics were held every week. Follow-up work is studiously carried out at these and valuable clinical teaching afforded to the medical school. From a preventive aspect Dr. Ballantyne's work was of immense value, and in all administrative steps he walked in perfect harmony and coöperation with our very comprehensive municipal child welfare organisation. Dr. Ballantyne's very thorough work and persistent efforts in antenatal work will never be forgotten.

I am, Sir, yours faithfully,

WM. ROBERTSON,

Edinburgh.

Feb. 5th, 1923.

THE PREVENTION OF HEART DISEASE.

To the Editor of THE LANCET.

SIR,—The interesting dissertations on heart affections in THE LANCET of Feb. 3rd impel me to offer a few comments.

In the first article by Dr. F. J. Poynton we are told that "we cannot at present, from clinical observation, tell when a cardiac valve is soundly healed." The inference is that we cannot tell in many cases when the valve is diseased. Does this incapacity on our part matter? Drs. J. Cowan and J. K. Rennie tell us that in 19 cases out of 81 in which valvular affections were present death was due to other factors, whilst in 39 others an additional endocarditis had to be introduced to aggravate the cardiac condition before death ensued. Drs. Cowan and Rennie state that in paroxysmal tachycardia cardiac failure occurs on account of the simultaneous contraction of auricles and ventricles, yet agree that heart-block may exist for ten years without serious complications. They argue that in heart-block synchronous contraction may occur but only occasionally. Surely if the "contraction" of the auricles is of any import even in a 2 to 1 heart-block, one or other of the auricular contractions must occur when the ventricle is in contraction.

In my opinion this forcible contraction is overrated; the chief function of the auricular fibres is to keep the blood properly reservoired in a taut organ anticipatory of the ventricular action. This tautness is assisted by the support obtained from the negative intracardial pressure, and my experience has been to find at post-mortem examinations of all cases of heart failure that this pressure has become atmospheric. Dr. Poynton objects to calling tendencies diseases, but a man is made up of tendencies, and without a man disease does not exist.

If, as you rightly point out, prevention is of fundamental importance, then our energies should be directed to investigating thoroughly all those factors which go to the making of a constitutional tendency. To do this, however, we require the coöperation of everybody who is interested in medicine and sanitation; of the general practitioner as well as the specialist, of the educationist as well as the member of every local health committee. Clean, wholesome food, handled by healthy persons in a cleanly manner, is essential both directly and indirectly for the good of the people, but to do this we need to place our educational methods on a satisfactory basis.

I am, Sir, yours faithfully,

Swansea. G. ARBOUR STEPHENS.

A TECHNIQUE OF SPINAL ANALGESIA FOR LAPAROTOMY.

To the Editor of THE LANCET.

SIR,—In further reference to the topic raised in your columns on Jan. 20th by Dr. S. A. Lane, and commented upon by my old friend Dr. C. F. Hadfield in your issue of Feb. 3rd, may I say that at the suggestion of Mr. Percival Cole I was using this combination of hyoscine with spinal anæsthesia at the Cancer Hospital in 1916? Quite probably we had been anticipated by others elsewhere, but at any rate we can claim to have been among the early workers in this field of anæsthesia.

I am, Sir, yours faithfully,

HENRY ROBINSON.

Bramham-gardens, S.W., Feb. 8th, 1923.

PARATHYROID AS A PROPHYLACTIC.

To the Editor of THE LANCET.

SIR,—Since March, 1922, I have been investigating the effect of parathyroid as a prophylactic for nasal and aural discharges following an attack of scarlet fever. In the small fever hospital of which I am medical officer a vast amount of expense and trouble has been caused by delay in discharging scarlet fever cases owing to the onset and persistence of such discharges. I first tried the effect of calcium lactate by the mouth without results. Since using the parathyroid, however, one case only has developed a discharge (nasal). This ceased within ten days. I have not yet had an opportunity to work out the statistics, and in any case the figures of such a small institution as ours would be quite inconclusive. I intend, however, to persist until I have collected a much larger number of cases, and in the meantime I shall be pleased to hear from any other who is investigating the subject.—I am, Sir, yours faithfully,

A. GORDON WILSON, M.B.,

Medical Officer, Penistone Isolation Hospital.

Feb. 2nd, 1923.

DIAGNOSES ON HEALTH INSURANCE CERTIFICATES.

To the Editor of THE LANCET.

SIR,—I should like to draw attention to the way in which National Health Insurance certificates are treated with regard to diagnoses. On several occasions patients have returned and asked me to change the diagnosis on their certificates or payment will not be given. In these cases my diagnosis frequently was "cold in the head," and in each case when I changed it to "coryza" or "nasal catarrh" payment was allowed. I would like to know the cause of this, and why also such diagnoses as "debility" and "anæmia" are refused. In a large number of cases which occur in panel practice it is impossible to make an accurate diagnosis at the time the first certificate is given, and both these terms are very often the best way of describing the condition present, instead of labelling the patient with a spot diagnosis which may prove wrong afterwards. These terms may not be very precise or descriptive, but surely they are on an equal standing with such diagnosis as "injury to limb," which is frequently given and accepted.

I am, Sir, yours faithfully,

Worksop, Notts, Feb. 5th, 1923. BEAUFORT BURKE.

THE CASE OF MADELEINE SMITH.

To the Editor of THE LANCET.

SIR,—I have read with interest the paper by Sir William H. Willcox in your journal of Jan. 27th. On p. 167 the author states that Madeleine Smith was condemned to death in 1857. Reference to a description of the evidence in "Report of the Trial of Madeleine Smith, 1857," by Alexander Forbes Irvine, advocate, states that the verdict was: (1) Not guilty on first charge; (2) not proven on second charge; (3) not proven on third charge. She was discharged.

I am, Sir, yours faithfully,
T. W. LOVETT.

Lower Broughton, Manchester, Feb. 2nd, 1923.

"LUNACY REFORM."

To the Editor of THE LANCET.

SIR,—The Executive Committee of the Lyceum Club have received complaints from members of the manner in which the "Lunacy Reform" dinner on Jan. 24th was conducted. They feel they must offer an apology to the many distinguished guests who were invited to a dinner to hear an address on a contentious subject without notice having been given beforehand or any adequate opportunity afforded for replies from those who held other views. The organisation of the dinner was in the hands of a very few members, who were entirely responsible for the arrangements. The members of the Executive can only regret the blunder and apologise for discourtesy which was certainly not intended.

I am, Sir, your faithfully,
H. L. GUY,
Secretary.

Lyceum Club, Piccadilly, W., Feb. 6th, 1923.

Obituary.

JOHANNES ORTH,

PROFESSOR OF PATHOLOGICAL ANATOMY IN THE UNIVERSITY OF BERLIN; DIRECTOR OF THE CHARITÉ CANCER INSTITUTE.

Johannes Orth was born at Wallmerod, a small village in what was then the Duchy of Nassau, and was the son of a doctor. Orth studied at Heidelberg, Würzburg, and Bonn. He qualified in 1871, and became assistant to his relative E. Rindfleisch, and later for five years to Virchow. He then went to Berlin, where his duties included the teaching of histology as well as pathological anatomy; a late outcome of this period of his life was an excellent manual on histology. His appointment to the chair of pathology at Göttingen was at first unpopular, since his brusque and decisive manner formed a contrast to that of his urbane predecessor, Emil Ponfick. However, he soon achieved success as a teacher and organiser, as well as esteem for his original work. He built a new institute, and wrote works on general and special pathology that remained classical reference books for many years. On the death of Virchow in 1902 he was called to succeed him as director of the Berlin Pathological Institute. Here also he created a new institute and reorganised the teaching, and yet found time for other activities on wider medical lines. He became a member of the Akademie der Wissenschaften, of the senate of the Kaiser Wilhelm Institute, chairman of the Central Committee for Cancer Research, and of the Berlin Medical Society. He worked for the institute he directed with increasingly successful results until, in 1915, he became ill and had to submit to operation, happily not for the carcinoma of the gall-bladder from which he had believed himself to be suffering. In 1917, at the age of 70, he resigned his teaching work, not on grounds of ill-health, but of increasing age, and he recovered speedily from the occasional attacks of biliary colic from which he suffered; subsequently he took great interest in the progress of the inflammation of the gall-bladder and liver which he diagnosed as his complaint, and according to Dr. O. Lubarsch[1] the post-mortem lesions corresponded with his prophesies. Johannes Orth was one who saw clearly, was conscientious, punctual, and precise in all that he undertook. He inspired respect and admiration even from those who feared his sharp incisive way of disposing of problems too much to seek his advice. In his relations with his family and chosen friends he showed his sensitive and loyal nature. His influence on the pathological outlook of our own time was widespread, his pupils including Aschoff, Kaiserling, Gaylord, Fibiger, and many others whose names are famous. He taught accuracy, thoroughness, and breadth of view, and his work will not soon be forgotten.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. W. H. Pope is placed on the Retd. List with the rank of Surg. Capt.

ROYAL NAVAL VOLUNTEER RESERVE.

E. E. D. Gray (late Surg. Prob.) to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. A. E. Hamerton is appointed Assistant Director of Pathology in succession to Lt.-Col. D. Harvey, Deputy Director of Pathology, who relinquishes temp. rank of Col.

Maj. A. H. Bond is placed temp. on the half-pay list on account of ill-health.

Capt. Carl K. G. Dick retires, receiving a gratuity, and is granted the rank of Maj.

ARMY RESERVE OF OFFICERS.

Army Dental Corps.

Capt. C. C. Marston, late Spec. List, to be Capt.

ROYAL AIR FORCE.

H. E. H. Tracy is granted a temporary commission as a Flight Lt.

Medical News.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on Jan. 24th it was announced that Dr. E. H. Starling had resigned from the Jodrell Chair of Physiology at University College, on his appointment as Foulerton Research Professor of Physiology. It was resolved to institute a University Readership in Cultural Anthropology tenable at University College.

Closing of the Physiological Laboratory.—It was resolved: (1) That after the end of the present session no University funds be devoted to the continuance of the Physiological Laboratory; (2) that negotiations be entered into with one or more colleges or schools of the University in order, if possible, to transfer members of the staff of the Physiological Laboratory at South Kensington to the staffs of other physiological laboratories; (3) that the Physiological Laboratory Committee be authorised to negotiate for the disposal of the laboratory apparatus, including fixtures and furniture, belonging to the University.

University Studentship in Physiology.—A University Studentship in Physiology, of the value of £50 for one year, will be awarded to a student qualified to undertake research in physiology, and will be tenable in a physiological laboratory of the University or of a school of the University. Applications must be received by the principal officer on or before May 31st, 1923. Full regulations for the award of the studentship may be obtained on application.

Publication Fund.—A small publication fund has been instituted for the purpose of facilitating the publication of (1) advanced lectures given at the University, (2) students' theses, (3) the results of research by members and teachers of the University. Assistance may take the form of a grant towards the expense of press work (including "offprints") or illustrations, or both.

Lectures on Mental Deficiency.—In accordance with a request from the Council of the Central Association for Mental Welfare, it has been decided to hold a course of lectures on mental deficiency for medical men at the central buildings of the University from May 28th to June 2nd, 1923, the arrangements being made by the Council of the Association in consultation with the University Extension Board.

---

[1] Medizinische Klinik, Feb. 4th.

University of Birmingham.—The annual meeting of the court of governors was held on Feb. 8th, the Vice-Chancellor, Sir Gilbert Barling, presided. In the course of his address the Vice-Chancellor drew attention to the scheme for research in mental diseases under the joint auspices of the University and the Asylums Committee of the city. He regarded this scheme as a most promising and valuable one. Prof. Grant Robertson also spoke, appealing for increased support from local authorities in the Midlands for the University.

Royal College of Surgeons of England.—An ordinary Council meeting was held on Feb. 8th, Sir Anthony Bowlby being in the chair.—A report was read from the Court of Examiners respecting candidates found qualified for the diploma of Membership, and diplomas were granted to 135 candidates mentioned in the report.—A report was read from the secretary to the Conjoint Examining Board respecting candidates found qualified for the diploma in Ophthalmic Medicine and Surgery, and diplomas were granted to 13 candidates mentioned in the report.—It was recommended that an afternoon reception be held at the College on June 6th for the delegates attending the 800th anniversary of the foundation of St. Bartholomew's Hospital, and that a conversazione be held on the evening of July 19th for the Members of the Congress of the International Society of Surgery.—The President reported that he had given Sir Arthur Keith, the conservator of the Museum, extension of leave till Feb. 24th, and that his Hunterian lectures would be delivered on March 5th, 7th, 9th, 12th, 14th, and 16th. The subject of the lectures will be "Man's Posture—Its Evolution and Disorders."—Mr. W. G. Spencer had been appointed Bradshaw lecturer for the ensuing year.—The resignations of Mr. James Sherren from the Court of Examiners and of Mr. F. F. Burghard from the Council were accepted with regret. The vacancy on the Court of Examiners will be filled at the ordinary Council meeting on March 8th.—The President reported that a meeting of Fellows would be held at the College on July 5th for the election of four Fellows into the Council in the vacancies occasioned by the death of Sir Charles Ryall, by the resignation of Mr. Burghard, and the retirement in rotation of Sir Charters J. Symonds and Sir Herbert Waterhouse. Notice of the meeting would be given to the Fellows by advertisement and by circular on March 9th, and March 19th would be the last day for the nomination of candidates. A voting paper would be sent on April 3rd to every Fellow of the College whose address is registered at the College.

Southampton Borough Council: Salaries of Medical Officers.—There was reference in our issue of Jan. 13th (p. 109) to this council's attempt to advertise in the medical press for an assistant medical officer and a school dentist at salaries of £450 each. *The Lancet* and the *British Medical Journal* having declined to publish the advertisement, the council proceeded to advertise in the lay press. Alderman Blatch, chairman of the Health Committee, has stated that a number of applications had been received for the post of dentist, but that only three applications had been received for the post of assistant medical officer, two of which were from unqualified persons. If the selected candidate is qualified he will be appointed. Three dentists have been asked to attend. The council decided to allow the Health Committee to make the appointments. The council also discussed the position with regard to the salaries of the medical officer of health and the chief sanitary inspector. These officers were served, like other servants of the corporation, with notices of a salary reduction of 10 per cent. It was then pointed out by the Ministry of Health that the council could not alter the appointments of these officers without the Ministry's consent. The Mayor now told the council that until the notices had been withdrawn the Health Committee could not ask for the Ministry's consent to the "cut." The committee recommended the withdrawal of the notices. Alderman Kimber said the trouble had arisen because the members of the council were ignorant of the existence of the Medical Officers of Health Act. The salary of the medical officer of health for Portsmouth had been reduced by £450. He moved an amendment that a deputation be sent to the Ministry of Health. Mr. P. V. Bowyer seconded. Mr. T. Lewis, J.P., a Labour member, said a mistake had been made, and the decent thing to do was to correct it by withdrawing the notices. Alderman Dr. Rogers pointed out that the Act referred to was only an amplification of one that had existed for many years. The council had acted first and thought afterwards. Mr. T. McDonnell said that if a deputation were sent they would see how far a Government elected on economy would try to prevent a local authority from economising. The Mayor remarked that at Portsmouth the medical officer had received a far higher salary than the medical officer at Southampton, and had no port sanitary work. The amendment was withdrawn, and the council decided to recall the notices.

Medical Society for the Study of Venereal Diseases.—The next meeting will be held on March 23rd, at 8.30 P.M., at 11, Chandos-street, London, W. 1. A discussion will take place in respect to Syphilis and Marriage.

Eugenics Education Society.—A lecture on Intersexuality and Sex Reversal will be delivered by Dr. L. Hogben, at the rooms of the Royal Society, Burlington House, Piccadilly, on Feb. 23rd, at 5 P.M., Major Leonard Darwin presiding. Members of the society and all interested are invited to attend.

Royal College of Physicians of Edinburgh.—A quarterly meeting of the College was held on Feb. 6th, Sir Robert Philip, President, in the chair. Dr. James Burnet and Dr. Disney Hubert Dusch Cran were admitted Fellows of the College. Drs. John Farquhar Christie, William Glen Liston, C.I.E., William Nicol Watson Kennedy, O.B.E., Max Lipschitz, and Robert McCall Burnie were admitted Members of the College. Dr. Robert Alexander Fleming was elected a Member of Council of the College in room of the late Dr. J. W. Ballantyne. Intimation was made of a bequest to the College by the late Dr. Harry Rainy of a valuable collection of works relating to Danté, and of a gift to the College by Mr. J. W. Fraser Tytler, W.S., of a bust of the late Dr. James Gregory.

Medico-Psychological Association of Great Britain and Ireland.—The next quarterly meeting of the Association will take place on Feb. 22nd, at the City Mental Hospital, Gosforth, Newcastle-on-Tyne, under the presidency of Prof. G. M. Robertson. Two discussions are arranged: (1) The Future Policy of the Association as Regards its Nursing Certificate and Examinations; (2) Special Appeal for Funds for the Prevention and Treatment of Insanity, and the Formation of the Council of Mental Hygiene. Superintendents of mental hospitals are reminded that there is a small convalescent fund for nurses who through sickness require assistance in their convalescence.

Presentation to Prof. Matthew Hay.—A committee has been formed for the purpose of presenting Prof. Matthew Hay, M.D., LL.D., medical officer of health for the City of Aberdeen, with his portrait or bust in recognition of the devoted and eminent services rendered by him to the city and University of Aberdeen during the last 40 years, as well as his powerful influence on the progress of preventive medicine and public health throughout the country. The appeal will be signed by Lord Provost Meff and Principal Sir George Adam Smith. Subscriptions, limited to 2 guineas, should be sent to the hon. secretary, Major H. J. Butchart, D.S.O., at Marischal College, University of Aberdeen.

Auxiliary Royal Army Medical Corps Funds. At a quarterly committee meeting recently held at the offices of the Funds grants were made to cases in the Benevolent branch for the orphans of officers amounting to £289 18*s.* 11*d.* and grants in the Relief branch for the widows and children of the rank and file, amounting to £717 13*s.* 6*d.* These Funds are for the relief of widows and orphans of commissioned officers, non-commissioned officers, and men of the rank and file of the Royal Army Medical Corps, Special Reserve, Territorial Force, and New Armies, and also for the relief of the children of those who have been so severely disabled in the late war, that they need help for the education of children. Requests for relief should be addressed to the hon. secretary, at the offices of the Funds, 11, Chandos-street, Cavendish-square, London, W. 1.

Sussex Throat and Ear Hospital.—A feature of the work of this hospital during 1922 was that the governors set themselves out to make their expenditure come as nearly as possible within their probable income. Thanks to the strictest economy, a legacy of £1500, payments from local authorities for such of the school-children under their care requiring treatment at the hospital, and fees for the assistance given to pensioners and other cases from the authorities, this aim has been largely carried out. In the annual report submitted at the general meeting on Feb. 5th the President, Lord Leconfield, however, emphasised from the chair that the hospital did not quite pay its way, and were it not for occasional legacies from former patrons and donations from benefactors the ordinary income would not be sufficient to meet the ordinary expenditure. Annual subscriptions during the year increased by £31 and payments from patients increased from £744 to £817, marking not only appreciation but willingness to pay. The governors referred again in their report to the numerous additions necessary to the hospital in order to make it perfect for the purposes for which it was erected, and while it was stated that the building on the east wing would not be undertaken until the money was received it was hinted that perhaps it might be put in hand next year. In-patients during 1922 numbered 572 and out-patients 1320.

THE Cambridge University Press announce the forthcoming publication of "Problems in Dynamic Psychology: A Critique of Psycho-analysis and Suggested Formulations," by Dr. John T. MacCurdy, Assistant, Psychiatric Institute of New York State Hospitals, and Lecturer on Medical Psychology, Cornell University Medical College, New York.

ASSOCIATION OF ECONOMIC BIOLOGISTS.—A general meeting of the association will be held at 2.30 P.M. on Feb. 23rd in the botanical theatre of the Imperial College of Science, Prince Consort-road, South Kensington, London, S.W. 7. Sir John Russell, F.R.S., director of the Rothamsted Experiment Station, and Mr. H. G. Thornton, head of the Bacteriological Department at Rothamsted, will open a discussion on "Partial Sterilisation of Soil: Present Views as to its Effects and their Causes."

SUSSEX EYE HOSPITAL.—The annual meeting of this hospital was held on Feb. 8th. The expenditure during 1922 amounted to £3051, and only by means of legacies amounting to £1600, against £350 during 1921, were the governors able to balance the accounts. Contributions from patients brought in during last year nearly £500, as compared to £207 in 1921; the number of in-patients was 294, as against 280; and of out-patients 3652, as against 3789.

ST. MARK'S HOSPITAL.—At the eighty-seventh annual general meeting of the governors of St. Mark's Hospital for Cancer, Fistula, and other Diseases of the Rectum, City-road, E.C., held on Feb. 8th, Mr. Robert Holland-Martin, C.B., treasurer, presiding, reference was made to a much-needed extension of the hospital premises on vacant land adjoining the present building. This extension, which would cost about £10,000, would provide accommodation for another 21 beds and a new out-patients' department, as well as for new pathological and X rays departments. During 1922, in which there had been a decrease of £431 in ordinary donations, the hospital had admitted 650 in-patients, of whom 581 had been cured. 3815 attendances had been made by 1130 new out-patients during the same period.

BRIGHTON AND HOVE HOSPITAL FOR WOMEN.—This hospital is one of the oldest of the institutions in Brighton, and was formerly known as the Lying-in Institution. It was founded in 1830, and until 1857 carried on its work in a small house in Middle-street, when it removed to more commodious premises in West-street. It was not until 1896 that surgical work was undertaken; since this time the demands upon the institution increased rapidly. In 1914 new premises were found, but these were soon commandeered by the War Office, and the Women's Hospital has only just been able to take possession. On Jan. 30th Princess Helena Victoria officially performed the opening ceremony. The property has been opened free from debt. In 1922 there were 382 in-patients, 1389 cases were visited in their own homes, and 638 out-patients were attended. As a training school for midwives the hospital has a high percentage of successes among the candidates sent up for the certificates of the Central Board.

ENCEPHALITIS LETHARGICA AND CEREBRO-SPINAL FEVER.—A circular has been addressed to medical officers of health by the chief medical officer of the Ministry of Health stating that special forms of inquiry as to cases of encephalitis lethargica need no longer be filled out. Detailed information has already been supplied in respect of 1250 cases or suspected cases of this disease, and this has formed the basis of report No. 11 (H.M. Stationery Office, 10*s.*), recently published. Medical officers of health are reminded that the Ministry undertake the examination of cerebro-spinal fluid in cases of suspected cerebro-spinal fever. The research work being undertaken by Dr. E. G. D. Murray for the Medical Research Council on the production of an immune serum for therapeutic purposes has been retarded by the scarcity of material, and pathologists isolating meningococci from the cerebro-spinal fluid, are asked to send cultures of freshly isolated strains to Dr. Murray at the Field Laboratories, Milton-road, Cambridge. Outfits for this purpose may be obtained on application to the Medical Research Council, 15, York Buildings, Adelphi, London, W.C. 2.

INDEX TO "THE LANCET," VOL. II., 1922.

THE Index and Title-page to Vol. II., 1922, which was completed with the issue of Dec. 30th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Feb. 20th.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for election of candidates.

PATHOLOGY: at 8.30 P.M.
Communications, &c.:
Dr. C. C. Okell and Miss E. M. Baxter: The Fermentation Reactions of Virulent *B. diphtheriæ.*
Dr. S. C. Dyke and Mr. C. H. Budge: The Inheritance of the Specific Iso-agglutinable Substance of the Red Cells.

Wednesday, Feb. 21st.

HISTORY OF MEDICINE: at 5 P.M.
Presidential Address: by Dr. Arnold Chaplin.
Paper:
Dr. W. Rees: The Social Effects of the Epidemics of the Fourteenth Century.

Thursday, Feb. 22nd.

UROLOGY: at 8.30 P.M.
Papers:
Mr. Ralph Thompson: The Propriety of Attempting Primary Union in Cases of Suprapubic Operations on the Bladder and Prostate.
Mr. Ogier Ward: Case of Air Embolism occurring during the course of urethroscopy.

Friday, Feb. 23rd.

STUDY OF DISEASE IN CHILDREN: at 4.30 P.M.
Clinical Meeting at Great Ormond-street Hospital for Sick Children.
Cases will be shown by the Staff.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.
Paper:
Sir George Buchanan: Recent Work of the International Health Offices.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.
THURSDAY, Feb. 22nd.—5 P.M., First Milroy Lecture:—Dr. W. G. Savage: Canned Foods in Relation to Health.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, Cavendish-square, W. (See Royal Society of Arts below.)
TUESDAY, Feb. 20th.—8.30 P.M., Dr. Godfrey Carter: The Medical Evidence in a Recent Murder Case (to be followed by a discussion). The Right Hon. Lord Justice Atkin will preside.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.
WEDNESDAY, Feb. 21st.—8 P.M., Mr. C. Ainsworth Mitchell: Handwriting and its Value as Evidence. Sir Richard Muir will preside and members of the Medico-Legal Society can obtain cards of invitation from Mr. Ernest Goddard.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE POST-GRADUATE LECTURES, 1, Wimpole-street, W.
THURSDAY, Feb. 22nd.—5.30 P.M., Dr. G. A. Sutherland: Cardiac Problems in Adolescent Life.
(At the Western General Infirmary, Marylebone-road, N.W.)
Fee for the course, £1 1*s.*; single lecture, pro rata.
TUESDAY, Feb. 20th.—5 P.M., Dr. B. Myers: Nutritional Disturbances of Infancy—Failure to Gain Weight, and Dyspepsia.
FRIDAY.—5 P.M., Dr. B. Myers: Decomposition (Marasmus, Atrophy, Malnutrition).

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
MONDAY, Feb. 19th.—11 A.M., Mr. Maingot: Surgical Wards. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.
TUESDAY.—10.30 A.M., Dr. Paterson: Demonstration of Medical Cases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.
WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12 noon, Dr. Burnford: Pathological Demonstration. 4 P.M., Mr. Donald Armour: Whitlow and its Treatment.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 12 noon, Mr. Simmonds: Demonstration of Fractures. 4 P.M., Dr. Castellani: Tropical Dermatology.
FRIDAY.—12 noon, Dr. Flett: Radiology. 2 P.M., Mr. Banks-Davis: Diseases of Nose, Throat and Ear. 3 P.M., Mr. Sinclair: Surgical Cases.
SATURDAY.—9 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10.30 A.M., Mr. Maingot: Surgical Pathology.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

TUESDAY, Feb. 20th.—4.30 P.M., Mr. L. Phillips: Investigation and Treatment of Dysmenorrhœa.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: JAN.–MARCH, 1923.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Feb. 19th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Lecture:—The Control of Ocular Movements: Mr. Leslie Paton.

TUESDAY, Feb. 20th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—The Significance of Ocular Phenomena: Dr. Risien Russell.

THURSDAY, Feb. 22nd.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Lecture:—The Symptoms of Cerebral Tumour: Dr. Gordon Holmes.

FRIDAY, Feb. 23rd.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Aural Vertigo: Mr. Sydney Scott.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

NEURO-PATHOLOGY.

MONDAY, Feb. 19th.—12 noon, Tissue Reactions in Disease of the Nervous System: Dr. J. Godwin Greenfield.

N.B.—A Course of Lectures in the Anatomy and Physiology of the Nervous System will be given if there are sufficient entries for it.

The fee for the whole Course, including Anatomy and Physiology, is £12 12*s.*; but these Lectures may be taken separately for a fee of £4 4*s.* Course without Anatomy and Physiology Lectures will be £10 10*s.* Any part of the Course may be taken separately at a special fee. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.

C. M. HINDS HOWELL, Dean of Medical School.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Feb. 22nd.—4 P.M., Dr. Heald: The Benefits and Uses of Electro-Therapeutics.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

THURSDAY, Feb. 22nd.—5 P.M., Chesterfield Lecture:—Dr. W. Knowsley Sibley: Seborrhœa and Psoriasis.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

TUESDAY, Feb. 20th.—4.15 P.M., Mr. H. H. Rayner: The Treatment of Empyema.

FRIDAY.—4.15 P.M., Mr. J. Morley: Applied Anatomy of the Gastro-intestinal Tract.

ST. MARY'S HOSPITALS, MANCHESTER. POST-GRADUATE LECTURE (Whitworth-street West Branch).

FRIDAY, Feb. 23rd.—4.30 P.M., Dr. Bride: Contracted Pelvis.

SALFORD ROYAL HOSPITAL. POST-GRADUATE LECTURE.

THURSDAY, Feb. 22nd.—4.30 P.M., Mr. Jefferson: Some Points in the Surgery of the Spine.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Feb. 21st.—4 P.M., Colonel L. W. Harrison, R.A.M.C. (retd.): The Organisation and Administration of Venereal Disease Schemes.

Appointments.

MITCHELL, A. O., M.R.C.S., L.R.C.P.Lond., has been appointed Resident Medical Officer to the Croydon Borough Hospital.

RUSSELL, V. I., M.D., B.S. Lond., Assistant Obstetrician to the Elizabeth Garrett Anderson Hospital.

SHARPLEY, J. E., M.R.C.S., L.R.C.P.Lond., reappointed Medical Officer of the Blyborough District, Gainsborough.

SINGLE, M., M.B., Ch.B.Manch., Junior House Surgeon at the Manchester Royal Eye Hospital.

Certifying Surgeons under the Factory and Workshop Acts: **KYLE, V. B.**, M.D.Dub. (Torrington); **ATTENBOROUGH, C. H.**, M.B., B.S.Lond. (Camberley); and **GAMESON, L.**, M.B., B.Ch. Oxf. (Okehampton, Devon).

Vacancies.

For further information refer to the advertisement columns.

Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H.S. £175.

Bradford Royal Infirmary.—Two H.S.'s. £150.

Burnley County Borough.—M.O. for Ven. Dis. £850.

Cardiff, King Edward VII. Welsh National Memorial Assoc.—Asst. Tuberculosis P. £500.

Derbyshire Hospital for Sick Children.—Res. M.O. £150.

Enfield, Middlesex, War Memorial Hospital.—Hon. Radiologist.

Greenwich Metropolitan Borough.—M.O. for Maternity and Child Welfare Work. £643.

Hospital for Women, Soho-square, W.—Res. M.O. £100.

London County Mental Hospital Service.—Seventh Aset. M.O. £449.

London Homœopathic Hospital, Great Ormond-street, W.C.—Res. M.O. £100.

Maidstone, West Kent General Hospital.—H.S. £220.

Manchester Children's Hospital, Pendlebury.—Res. M.O. £80.

Manchester University.—Demonstrator in Path. £300.

Manchester, Whitworth Park Hospital.—Res. Surg. O. £250. Also H.S.'s. £100 each.

Nottingham General Dispensary.—Res. Surg. £300.

Rochester, St. Bartholomew's Hospital.—Hon. Radiologist. £52.

Rotherham Hospital.—Jun. H.S. £150.

Royal London Ophthalmic Hospital, City-road, E.C.—Sen. H.S. £150.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. P. to Skin Dept.

Southampton, Royal South Hants and Southampton Hospital.—Jun. H.S. £150.

Swansea General and Eye Hospital.—H.P. £200. Also H.S. for Ophthalmic, &c., Depts. £200.

West End Hospital for Nervous Diseases, Regent's Park, N.W.—Senior H.P. £150. Also Jun. H.P. £100.

Births, Marriages, and Deaths.

BIRTHS.

CREASY.—On Feb. 6th, at Ashley-gardens, S.W., the wife of Dr. Rolf Creasy, jun., of a son.

GEBBIE.—On 9th inst., to Dr. and Mrs. N. Gebbie, Boston Bank, Hyde, Cheshire—a daughter.

GRANT.—On Feb. 6th, at the Manor House, Wilnecote, Tamworth, the wife of Dr. J. V. L. Grant, of a son.

JACKSON.—On Feb. 6th, at Hatherley-road, Sidcup, the wife of Dr. T. Jackson, of a daughter.

MARTYN LOBB.—On Feb. 5th, to Louise Josephine, the wife of E. L. Martyn Lobb, M.S., F.R.C.S., of 11, King-street, Maidstone—a daughter.

VERDON.—On Feb. 2nd, at a nursing home, Cambridge, the wife of Captain P. Verdon, I.M.S., of a son.

MARRIAGES.

DIXON—GOODALL.—On Feb. 2nd, Gerald Conroy Dixon, B.A. Oxf., M.B., Ch.B. Manch., to Margaret Goodall, of Belmont, Dunfermline.

KIDD—CHALMERS.—On Feb. 7th, at St. Columba's (Church of Scotland), London, Dr. W. Shirley Kidd, of Harrogate, to Isla Scott Chalmers, of Addison-road, London.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE TRAINING OF WELFARE SUPERVISORS.

By A. C. Marshall, M.A., LL.B.,
PRESIDENT OF THE WELFARE WORKERS' INSTITUTE.

The plea for the establishment of a centre for training welfare supervisors is opposed to the best traditions of the professions. The various universities are established to train doctors, lawyers, engineers, and so forth. Why should they not be capable of training aspirants to the youngest of the professions, that of industrial welfare supervisors? That they suffer under no disability in this respect is shown by the close connexion there has been for several years between the Welfare Workers' Institute and the various universities with special courses in social science. And through such close coöperation between those actually engaged in the work and the universities splendid results have been attained. Industrial welfare work, is after all, one of the many agencies for the improving and uplifting of humanity, and those guiding it must have a broad outlook and a wide general culture. There is a distinct danger in permitting any centre established by industrial magnates to control the training of entrants to the profession. In the best interests of the welfare movement, industry as a whole, and the community generally, the training of welfare supervisors must remain unquestionably in the hands of the universities.

The Welfare Workers' Institute.

The Institute is naturally keenly desirous that all entrants to the profession shall maintain a high standard of qualification and training. It therefore stipulates that anyone wishing to become a member must hold the diploma or certificate of one of the training courses approved by the institute, unless possessing other qualifications which in the opinion of the Executive justify an exception being made. We cannot yet, of course, control the admission of supervisors into industry, but employers of labour and others interested would be wise if they insisted that all entrants conformed to the regulations for admission to the Institute. In that would lie a big safeguard that the movement in their works should proceed on sound lines.

Training Courses.

The Institute has approved the training courses provided by the following universities: Birmingham; Bedford College, London; Bristol; Edinburgh; Glasgow; Leeds; Liverpool; London School of Economics; College of Technology, Manchester (long course only); St. Andrews University (Dundee College); Woodbroke Settlement, Birmingham.

The London School of Economics gives special attention to welfare students, their practical work and coaching being undertaken by experienced welfare workers. Glasgow University provides the only recognised course, the lectures for which are all given in the evening. They are especially intended for social workers who are already in work and who wish to become more highly qualified.

Birmingham is especially well situated for those who wish to study the growth of the industrial system from the domestic workshop to the most highly organised industrial concerns. Woodbroke is not a settlement in the ordinary sense of the word, but a college for the study of religious and social problems. It caters especially for the social student who has done a good deal of practical work, or for the tired social worker who wishes to leave work for a short time of quiet study. Bristol has an interesting course and, like the London courses, has a part-time welfare tutor who is a member of the Institute. Edinburgh has not the opportunities for extensive industrial training afforded by some of the universities, but gives the student intensive training in particular factories. Leeds has a unique system of training in the economics of the different important trades of the country, such as engineering or textiles.

Liverpool University, which works in close conjunction with the local branch of the Institute, caters especially for those students who are particularly interested in psychology, and has an admirable system of coöperation with the various municipal and charitable societies. Courses of lectures and practical work are carried out by welfare workers. St. Andrews University, Dundee, makes a special point of introducing the student to the practical working of the machinery of government of a modern city.

The College of Technology, Manchester, has only recently established the full course required by the Institute, but can afford the student admirable facilities for observing the principles of welfare work in many kinds of factories. This course, or the Leeds course, should be chosen by students wishing to take up work in textile factories. Bedford College, London, has only recently been recognised after representations made by the Institute with regard to practical work and welfare lectures.

Social Studies Board.

Through the Joint Social Studies Board of the universities and the activities of the Welfare Workers' Institute, there is an active mutual interchange of ideas regarding the various courses, so that, while individuality is maintained, the courses are conducted in a broad, general way on similar lines. It is thus obvious that the establishment of a special centre for training welfare supervisors would be superfluous. Far better would it be for benevolently disposed individuals to strengthen the social science departments of the universities by endowments, as has recently been done in the case of Liverpool by the establishment of the Charles Booth Chair of Social Science.

JENNER CENTENARY COMMEMORATIVE EXHIBITION.

The exhibition of Jenner relics now on view at the Wellcome Historical Medical Museum, 54a, Wigmore-street, London, contains numerous objects of interest in connexion with Jenner and his work. Prominent among these are various original coloured drawings of vaccine pustules made for Jenner, and a set of reproductions of Kirtland's coloured drawings illustrating vaccination and variolation from the second to the sixteenth day, the latter series having been presented to the Museum by Sir Dawson Williams. Copies of the first (1798) and second (1800) editions of the "Inquiry into the Causes and Effects of the Variolæ Vaccinæ," may be seen, together with foreign translations and works which followed its publication, and various books dealing with the sum of knowledge concerning small-pox prior to Jenner's great experiment. Numerous autograph letters relating to the supply, use, and results of vaccination have been collected; among them are several referring to the grants proposed and made to Jenner by Parliament. An interesting series of caricatures and cartoons, in the coarse but telling manner of the early nineteenth century, illustrates the bitterness of the anti-vaccination movement; included among them is James Gillray's satirical drawing "The Cow-pox, or the wonderful effects of the new vaccination," showing small cows sprouting from various parts of the bodies of vaccinated persons. Of more personal interest are Jenner's favourite armchair, in which his fatal seizure came upon him, and his original lancets and scarificators, together with pocket scales, cupping-glass, seal, walking-stick, snuff-box, &c. A considerable number of portraits of Jenner has been assembled; these include oil paintings, engravings, and line and wash drawings, together with a handsome, though damaged, miniature in wax, modelled from life by T. R. Poole in 1808 and set as a medallion. The bronze group by Monteverde, of which we gave an illustration in our issue of Jan. 20th, occupies the centre of the space reserved for the exhibition. The exhibition will remain open for several months.

IN MEDICAL TOUCH WITH RUSSIA.

Dr. Melville D. Mackenzie, reporting to the Friends' Relief Committee (10, Fetter-lane, London, E.C. 4), states that he has opened a bacteriological laboratory at Buzuluk, where during the first seven weeks 2245 examinations have been made. Its presence is greatly appreciated by the local doctors, who are learning to employ it as a means of diagnosis. With a view to getting full use made of the laboratory and to invigorate the local medical work, a series of weekly demonstrations and lectures have been given by the medical officer on Monday nights. All the medical practitioners in the town are invited; a lecture is first given on some special subject and the remainder of the evening is spent in discussion. These meetings are appreciated by medical men who have had no opportunity of getting into touch with recent medical work since 1914. The subjects dealt with have been the use of a laboratory for diagnosis, various special groups of bacteria, and outlines of anti-tuberculosis measures. A local doctor is reading a paper on the treatment of typhus, and the local surgeon is following this by a paper on the surgical complications of typhus fever.

It is difficult, writes Dr. Mackenzie, to imagine the desire for new knowledge that results from starvation of all forms of literature for a period of eight or nine years. Scientific men in England may be glad to help by making it possible for the doctors working in these outlying districts to obtain books and journals. Any such gifts should be in the form of money, as none of the doctors at Buzuluk can read English.

A lecture on religion and medical sociology will be given at 8 p.m. on March 2nd at 11, Chandos-street, London, W., by Dean Inge. The lecture is being held under the auspices of the Marylebone Division of the B.M.A. and medical men and women will be welcomed.

New Principles IN THERAPEUTIC INOCULATION.

Based on Research Work done in Collaboration with

L. COLEBROOK, M.B., B.S. LOND.,

AND

E. J. STORER, M.R.C.S. ENG., L.R.C.P. LOND.

Being an Expansion of a Lecture delivered at a Special Meeting of the Royal Society of Medicine on Nov. 30th, 1922,

BY SIR ALMROTH E. WRIGHT, M.D., F.R.S.

PART I.*

Pasteur was the first to think out the principles involved in Jennerian vaccination, to show how these could be applied to bacterial infections, and to conceive the idea of prophylactic inoculation against all infective diseases.

The tenets he laid down—let me in view of what is to follow speak of them as Code No. 1 or the original Pasteurian Code—may be set out somewhat as follows:—

CODE NO. 1.—THE ORIGINAL PASTEURIAN CODE.

1. The essential preliminary to any prophylactic procedure is to possess ourselves of the pathogenetic organism, or if this is as yet undiscovered of the virus that contains it, and to manufacture a vaccine from this.
2. The vaccine must consist of living germs; but these must, with a view to the risk that would attach to the employment of virulent material, be attenuated.
3. When an appropriately attenuated vaccine—that is, a vaccine which can be warranted to produce only a moderate clinical reaction—has been obtained, the exact quantum implanted will not be of material importance.
4. Bacterial vaccines should be implanted subcutaneously.
5. Vaccination is applicable only to the uninfected.
6. The protection conferred by the vaccine is always specific—in other words, protection is obtained only against the species of pathogenetic agent of which the vaccine consists.
7. Protection is obtained only after the lapse of ten or more days from the date of inoculation.

By putting into practice these principles—and they relate, as you see, only to prophylaxis—great and notable successes were achieved. In particular, Pasteur succeeded in protecting sheep and cattle against anthrax. Later Ferran, and after him Haffkine, employing a much more exact technique, applied the Pasteurian methods to man in their anti-cholera inoculations.

In the meanwhile, impelled to do so by that "pain in the mind" which is felt when one is appealed to and is powerless, Pasteur had addressed himself to another problem in connexion with immunisation—the problem as to whether it would, by any application of vaccination, be possible to arrest the development of rabies in a patient bitten by a rabid animal. Here, of course, his principle that vaccination was applicable only to the uninfected suggested that nothing could be done. But emotional tension is intolerant of any intellectual impasse, and its special function in such circumstances is to insist on a critical probing of subsisting rules, and on a definition of all undefined or loosely-defined terms, and on a sharper focusing of all nebulous elements of thought. Here, therefore, it was bound inevitably to lead to a critical review of the principle that vaccination is applicable only to the uninfected, and to a general or sharper focusing of the terms "infected" and "uninfected." And then it was discerned by Pasteur—and afterwards, of course, by all the world—that a patient in whom the virus of rabies has been implanted should, pending the development of events, be reckoned as uninfected; and, further, that if it takes for a virus much more than ten days, and for protection after vaccination only about ten days, to develop, the patient is within that period a perfectly suitable subject for preventive inoculation.

This forward step in thought, with which Pasteur broke away from what had been handed down and also from what he himself had formulated, bestowed upon us the preventive treatment of rabies. It was, as we shall see, destined to lead also to therapeutic inoculation.

A Supplementary Article of the Pasteurian Code.

We may now complete the Pasteurian Code as set out above by adding to it this supplementary item.

8. Vaccination may be resorted to in the incubation period of a disease, provided that that incubation period has still more than ten days to run.

That brings to a close the great opening chapter of scientific immunisation—the chapter contributed by Pasteur.

THE NEXT ADVANCE IN IMMUNISATION—ANTI-TYPHOID INOCULATION.

We have seen in the foregoing that emotional tension conducts to a closer scrutiny and sharper focusing of ideas, and that it is by the clarification which results from such closer focusing that problems are resolved. This holds true over the entire domain of knowledge, and is again exemplified in connexion with the next two advances in the field of immunisation—those made in connexion with anti-typhoid inoculation. These improvements were (*a*) the substitution of dead for living vaccines, and (*b*) the preliminary gauging of the efficacy of prophylactic procedure by measurement of the anti-bacterial elements produced in the blood. Of these forward steps, the first was taken because of hesitation to risk inoculation with living typhoid bacilli; the second, from unwillingness to launch out with a vaccine of dead microbes without first obtaining proof of its efficacy.

The general progress of knowledge had already furnished certain facts and general inferences which bore on these issues. To begin with the conception that the antigens required were the metabolic products elaborated by microbes growing in the organism was becoming discredited, and was being gradually replaced by the conception that the antigens required were elements derived from the bacterial protoplasm. Again, the general principle—enunciated by Ehrlich in the apophthegm *corpora non agunt nisi soluta* was silently pointing to the conclusion that in vaccines the living or dead germs, as such, could not be the actual antigens; that these must be dissolved elements; and that the microbes in vaccines, whether they were dead or alive, could in reality be only mother substances of antigens. Lastly came the important fact that Pfeiffer had, by the incorporation of dead typhoid microbes into man, obtained a production of agglutinating substances. In consequence attention in the first anti-typhoid inoculations was focused upon the production of agglutinins.[1] But the measurement of these showed very little more than that an immunisation response was obtained by the incorporation of dead microbes. Measurements of the bactericidal power of the blood[2] were then undertaken, and it was these that brought illumination. They established that when quanta of typhoid vaccine which produce moderately severe constitutional disturbance are incorporated, inoculation is followed first by a negative phase, in which the bactericidal power of the blood is reduced, and then by a positive phase in which the bactericidal power may be increased as much as 1000-fold; further, that when doses which produce very severe constitutional disturbance are employed the negative phase is protracted, and in some cases perhaps indefinitely protracted; and lastly, that when doses which produce only trifling constitutional disturbance are employed a positive phase is obtained without the intervention of any negative phase, and the bactericidal power of the blood is already after an interval of 24 hours very considerably increased.

---

* Parts II. and III. will be published in coming issues.

[2] Wright: Changes Effected by Anti-typhoid Inoculation in the Bactericidal Power of the Blood, with Remarks on the Probable Significance of these Changes, THE LANCET, Sept. 14th, 1901.

These facts supply the principles which everywhere regulate—or perhaps it would be safer to say should everywhere regulate—anti-typhoid, anti-cholera, anti-pneumonia, anti-plague, and all other prophylactic inoculations.

Again, the observation that protective substances can be made to appear in the blood within 24 hours from the incorporation of a vaccine was one which carried consequences. It was deducible from this that the procedure of inoculation in the incubation period cannot be applicable only to rabies with its average incubation period of many months, but must, in theory, be applicable to typhoid and Malta fever with their incubation periods of a couple of weeks, and even—as contended by Haffkine—to plague with its incubation period of only a couple of days. But the full scope of application of the facts brought to light in connexion with anti-typhoid inoculation did not appear until the concept of an incubation period had been sharply focused, and until this had been seen to import a period when the microbe is cultivating itself in the body, not broadcast but confined in one region. Once that fact is regarded, there is, as you will see, no getting away from the conclusion that the successful event of the Pasteurian preventive treatment in rabies, and, it may be added, the occasional successful event of anti-plague inoculation administered in the incubation period of plague, must be due to immunising responses successfully evoked by the vaccine in the still uninfected regions of the body. That idea—the idea that the uninfected and still inactive regions of the body can by applying the stimulus of a vaccine be made to bring succour to the infected regions was, as you know, the mother idea of vaccine-therapy.

Now let me—for I shall want this as a point of departure for setting out my new matter—formulate in the form of a code the principles we have just been considering. The code now in question—for convenience of reference I call it Code No. 2—has been gradually elaborated in the Inoculation Department of St. Mary's Hospital. You will observe that here only the first, fourth, and seventh tenets have been taken over practically unmodified from Pasteur.

CODE NO. 2.—FOUNDED UPON A STUDY OF THE BACTERICIDAL AND OPSONIC CHANGES PRODUCED IN THE BLOOD BY THE INOCULATION OF VACCINES INTO THE PATIENT.

1. The essential preliminary to all immunisation procedures is to possess ourselves of the microbe of the disease, or failing that of its virus, and to employ this as material for the manufacture of the vaccine. And here it may be parenthetically pointed out that inasmuch as in prophylactic inoculation the vaccines are stock vaccines and give good results it cannot in any form of inoculation be theoretically essential to employ vaccines made directly from the patient.

2. Vaccines should in all cases where the microbe can be cultivated outside the body consist of sterilised cultures.

3. Vaccines may be turned to account in a variety of different ways. They may be employed not only for prophylaxis but also for preventive treatment in the incubation period of general infections. Again, they may be therapeutically employed in all localised infections other than those complicated by pyrexia and heavy and frequent auto-inoculations. In this last class of infections, and also in those septicæmic processes in which bacterial toxins in large quantity are circulating in the blood, vaccines are contra-indicated.

4. Bacterial vaccines should be incorporated hypodermically.

5. The quantum of vaccine incorporated is of supreme importance; it affects both the kind of response and the rate at which protective substances appear. With only small doses of vaccine, or comparatively light auto-inoculations, a positive phase—or as it may be better called, an epiphylactic or immunising effect—may be registered in less than 24 hours after the incorporation of the vaccine. A similar but evanescent increase, known as the false rise, may be registered within a couple of hours after larger doses of vaccine and heavier auto-inoculations. These larger inoculations of vaccine and heavier auto-inoculations produce after that very fleeting positive phase a negative phase or—for these are better terms—an apophylactic or de-immunising effect. And this effect is greater and lasts longer the larger the quantum of antigen carried into the blood.

6. In correspondence with the above the following rules of dosage may be laid down. In prophylactic operations undertaken in uninfected surroundings the dose should be that which evokes the optimum epiphylactic response, and it is for the attainment of that end permissible to employ doses which produce a temporary negative phase. When inoculating prophylactically in the presence of an epidemic, or in the incubation period of a general infection, and generally in the treatment of localised infections, reduced doses should be employed in order to avoid the constitutional disturbance and temporary aggravation of symptoms and dispersal of microbes in the organism. Reduced doses should also be employed where the chief matter of concern is to obtain with promptitude some clinical improvement.

All these rules can be summarised into one general principle—that the dose of vaccine incorporated should depend on the patient's being infected or uninfected, and that where he is infected the dose should stand in inverse relation to the volume of his infection.

7. The anti-bacterial substances elaborated in response to inoculation operate specifically upon the variety of microbe which has furnished the vaccine, but it is possible that in addition some collateral immunisation is achieved.

I cannot here attempt to give even a brief summary of what has been achieved by the following out of this newer code. To do so I should have to chronicle all that has in the last 20 years been achieved by prophylactic and therapeutic inoculation in connexion with bacterial disease. Instead of attempting that, let me fix your attention on the fact that, except in a few isolated instances, therapeutic inoculation has proved unavailing in pyrexial phthisis and in septicæmia. And I may again point out that it is in the nature of things that the failures here in question should evoke in some of those who have had over and over again to witness them the same emotional tension and the same closer focusing of ideas which led to Jennerian vaccination, to Pasteur's thinking out the principles of immunisation, to the extension of prophylactic treatment to human diseases, to the Pasteurian preventive treatment of rabies, to the treatment of diphtheria by antitoxins, to vaccine-therapy, and to therapeutic advances along other lines. All this is, as you have discerned, only a prelude to setting out to you the outcome of an inquisition into those universally accepted principles which have hitherto guided vaccine-therapy, and to telling you of certain new principles which have in the last few years gradually emerged.

I have here to choose between two different modes of exposition. I could start by describing the new technical procedures which have been devised, could then, in connexion with each method, tell you the new facts it has furnished, and could then leave it to you to make at the end your own generalisations. That would be like leading you along a number of new paths, showing you hurriedly a portion of what could be seen from each, and leaving it to you to build up from those glimpses a general map of the country. The alternative, and proper, method will be for me, who have been every day engaged in exploring these paths, to give you at the start the general scheme of the landscape and then afterwards to describe to you the methods of exploration and tell what each of these has yielded.

The new principles which have emerged will best be set out in the form of yet another code. This will be Code No. 3, and I would wish you, when taken aback at its subversive character, to observe that there is here a going back, not upon anything directly established by experiment, but only upon dogmata built upon a foundation of uncoercive inferences. I have in view here not only the tenets of the Pasteurian code, but also the doctrine of phagocytosis with its implication that leucocytes can kill microbes only by phagocytosis. I wish you also to bear in mind that the code here brought forward rests almost exclusively on experiments with the staphylococcus and streptococcus, that up to the present it has been put into actual operation almost exclusively in the treatment of infections by those microbes, and that the question of its application to prophylactic procedures is yet quite unstudied.

CODE NO. 3.—FOUNDED UPON A MORE DETAILED STUDY OF THE CHANGES PRODUCED IN THE BLOOD BY INOCULATION OF VACCINES IN VIVO AND IN VITRO.

1. While the nature of the infecting microbe should in every case be ascertained, it is not theoretically necessary that the vaccine employed in treatment or arrest of the incubating infection should be derived from the species of microbe which causes the disease. Sufficient justification for recourse to a particular vaccine is afforded when that vaccine has been shown to increase the antibacterial substances which operate upon the infecting microbe.

2. When vaccines in appropriate doses are added to the blood, whether in vivo or in vitro, instantaneous epiphylactic response is evoked, and the maximal response may be expected after only very short delay.

3. The epiphylactic response here in question consists in an extrusion of opsonic and bactericidal elements from the leucocytes. And it is mainly by this ectocytic chemical action, and only to an insignificant extent by phagocytosis and internal digestion, that the bactericidal action of the leucocytes is exerted.

4. The antibacterial substances here in question are polytropic—in other words, they operate not only upon homologous but also upon quite unrelated species of microbes.

5. Where the effective dose of vaccine for intravenous application has been ascertained, this method of administration is from considerations of certainty and rapidity of therapeutic action to be preferred to subcutaneous inoculation.

6. In septicæmias and other heavy bacterial infections the patient's leucocytes lose their power of responding to vaccines. In such cases it is essential before inoculating to satisfy one's self that the patient's blood still retains its power of epiphylactic response.

7. Where by reason of the poisoning of leucocytes active immunisation by means of vaccines is ruled out, the method of immuno-transfusion should be resorted to—in other words, healthy human blood which has made proper epiphylactic response should be incorporated.

Having now formulated the new principles arrived at, I must next show the data upon which these are founded. Those data were, as you will understand, obtained by adding measured quanta of vaccines or, as the case may be, living microbes, to the blood as a whole or to its separate element. Let me begin with a conspectus of the methods of blood examination which have here come into application.

CONSPECTUS OF METHODS OF BLOOD TESTING.

I. *Whole Blood.*
- (1) Measurement of hæmobactericidal power. (Bactericidal effect of the leucocytes and serum acting in conjunction.)
  - Implanting and explanting.
  - Implanting and inculturing.
- (2) Measurement of phagocytic power.
  - With defibrinated blood.
  - With washed leucocytes and serum (reconstituted blood).

II. *Serum.*
- (1) Measurement of serobactericidal power.
  - Implanting and explanting.
  - Implanting and inculturing.
- (2) Measurement of opsonic power.

III. *Leucocytes.*
- (1) Measurement of phagocytic efficiency.
- (2) Measurement of spontaneous emigration and chemotactic reactions.
- (3) Measurement of ectocyto-bactericidal power (i.e., power of killing extracellularly).
- (4) Measurement of opsonodoteric power (i.e., power of furnishing opsonins).

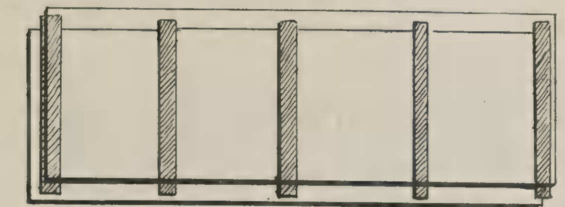
IV. Combined measurement of—

Phagocytic Power, Opsonic Power, and Phagocytic Efficiency of the Leucocytes.—*Chiastic procedure.*

A few words of general introduction and, in the case of those methods which have been newly devised, a brief description will be required. Let me deal first with the measurement of the bactericidal power of the whole blood.

Methods of Measuring the Hæmobactericidal Action.—This can be measured (1) by the *implanting and explanting procedure*, i.e., by bringing together measured volumes of defibrinated blood and graduated dilutions of a bacterial culture, and then after a fixed interval diluting with nutrient broth, and then either growing the surviving microbes in the broth-diluted blood, or explanting on to an agar surface. An alternative method of measuring the bactericidal power of the whole blood—available only when dealing with serophytic microbes—is (2) the *implanting and endo- or in-culturing procedure*. The principle of the latter method is to implant graduated quanta of microbes into the blood; to introduce the implanted blood into very fine capillary tubes, or, better, into "slide cells"; and to incubate, so as to let such microbes as survive grow out into colonies.

FIG. 1.

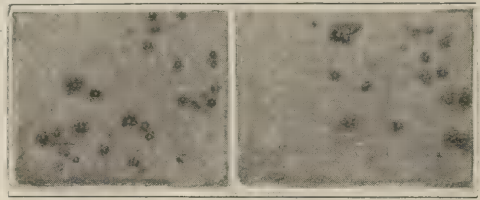


Slide cell ready for the reception of the implanted blood.

Slide Cells.—These are made from ordinary microscopic slides. We take a sterilised slide, place it with its convex side turned uppermost on the bench, and then provide confining walls for four compartments by taking strips of paper dipped in very hot vaseline, and laying these down at both ends and at equal intermediate distances along the slide. We then take another slide, hold it in the flame, concave side downwards, and then immediately press it down upon the vaselined strips. The paper employed for these strips must be of standard thickness so as to give blood films of appropriate and uniform depth. If the blood film is too thick the growing colonies are concealed, and if it is too thin the leucocytes are too remote from the implanted microbes—moreover, there is not a sufficient depth of red corpuscles to show up the colonies to advantage. A convenient depth of film is obtained by using for our strips a paper about 1/300 inch (1/12th mm.) in thickness. The detail of the procedure for measuring the hæmobactericidal power in slide cells is as follows: We begin by making a series of progressive dilutions of our bacterial culture. Then we measure out a series of 50 c.mm. volumes of defibrinated blood and introduce into each of these (from a calibrated capillary pipette drawn out at the extremity into a fine point) 2·5 c.mm. of one of the dilutions of our culture. Then after thorough mixing we introduce the implanted blood into one of the compartments of our slide cell. In preparation for this, the edges of the slide cell are re-sterilised by passing them through the flame, and the upper slide is pushed back a little so as to leave a projecting lower lip upon which to rest the point of the pipette which purveys the blood. When the compartments of the slide cell have been filled in with the allocated volumes of blood, the upper slide is brought back into position and the ends and sides are carefully sealed up by brushing them over with very hot melted paraffin wax. After 24 hours' incubation the staphylococcus colonies show up against the scarlet background of the blood by a surrounding dark purple discoloration. Then after a few more days this purple fades out and each colony is represented by a small bleached patch. (Figs. 2, A and B.) When instead of implanting into defibrinated blood we implant into a blood which coagulates in the slide cell, an additional feature arrests the attention. Each colony is encompassed by a ring. It is just as if we had taken an agar plate upon which staphylococcus colonies are growing, and a cork borer of much greater diameter than these, and had then, centring upon the colonies, cut into the medium and then withdrawn our cutting implement. It may be taken that the rings which encircle the staphylococcus colonies in the blood delimit the regions in which the fibrinous network has been digested by tryptic ferment generated either by the microbes or by the leucocytes which have gathered round them.

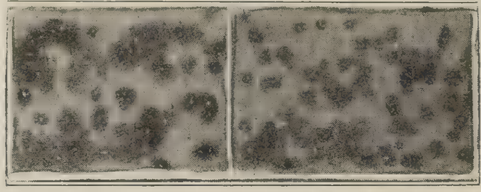
Reverting to the more general consideration of the measurement of hæmobactericidal power, it will be well before passing on to appreciate that the opportunity for phagocytosis afforded in the quiescent blood in vitro is certainly much greater than that afforded in the circulation. In that swift torrent the leucocytes have as little opportunity for ingestion as would fish if, instead of facing upstream, or swimming down faster than the current, they were only passively swept along side by side with all other flotsam. In the tranquil conditions provided in vitro the leucocytes will be able to congregate round their bacterial prey.

FIG. 2.—A.



Normal blood implanted with staphylococcus, showing the colonies which appear after 24 hours' incubation.

B.



Blood from a patient with streptococcic septicæmia implanted and cultivated exactly as above.

Methods of Measuring the Phagocytic Power of the Blood.—We may here add one volume of the microbic suspension to two volumes of defibrinated blood[3]—or, following out the opsonic technique more closely, we may take one volume of washed corpuscles from the blood that is to be tested, one volume of serum, and add one volume of the microbic suspension.

Methods of Measuring the Sero-Bactericidal Power.—Here, as in connexion with the whole blood, we have two methods at our disposal. We can, using the procedures described above in connexion with blood, implant and then explant. When dealing with serophytic microbes, in particular with the staphylococcus, we can also implant and inculture, filling our serum into fine capillary tubes and incubating in these.[4] (Fig. 3.) By this method we obtain, as is seen in the figure, quite compact and separate colonies. The number of these will, of course, correspond, in the case of a non-bactericidal serum, to the number of microbes implanted; and in the case of a bactericidal serum to the number of microbes left alive. We can accordingly by this procedure compare the bactericidal potency of two sera, and we can for further control in such measurements count also the colonies which develop in nutrient broth. But in the case of broth we must, because of the diffuseness of the colonies, limit ourselves to implantations of less than 100 microbes per 50 c.mm. volume, and must employ capillary tubes of such fineness that a 50 c.mm. volume may occupy a length of not less than 25 to 50 cm.; and above all, we must very carefully avoid all mechanical disturbances.

EXPERIMENTS: GRADUATED IMPLANTATIONS OF LIVING MICROBES INTO BLOOD IN VITRO.

Inculturing Experiments.—We may now, leaving till later what requires to be said about the remaining methods of blood testing, study what happens when we make graduated implantations of living microbes into blood. And it will here, as in all experimentation, be well to visualise and formulate quite clearly in advance what we expect will happen; for then both such results which conform exactly, and those which are at variance with expectation, will engrave themselves more deeply upon the mind.

Here, if anyone were required to say a priori what would follow upon making graduated implantations of living microbes into blood, he would assuredly say that as fewer and fewer microbes were added to blood a larger and larger percentage, and after a certain point a full 100 per cent. of the added microbes would be killed. Similarly he would predict of such graduated implantations that as more microbes were added the percentage of survivors would go up in a perfectly regular manner. The next step will be to see what does actually happen. Here a distinction has to be made between blood and blood. And I would ask you to let me tell you first what happens when I take my own blood and implant into it graduated quanta of microbes. I begin with my own blood because it so happens that this, by virtue of its having a subnormal number of leucocytes, and serum which has very little bactericidal action upon the staphylococcus, furnishes a specially favourable object for the experiments here in view. One of many dozens of quite conformable experiments made with the blood is set out in tabular form (Table I.). This particular experiment was carried out in duplicate by separate observers. The results of both workers are given.

It will be seen that we have here, with implantations of 10,000 to 150 staphylococci per c.cm., an average killing of 78·8 and 76·3 per cent. respectively; and with implantations below 150 staphylococci per c.cm. no killing at all—in other words with moderate implantations an average survival of 22 per cent., and with quite small implantations a survival of a full 100 per cent. These figures, I think, tell their tale quite plainly. Their import, as I read it, is that we have in the blood an apparatus for primary and an apparatus for secondary defence—aphylactic and epiphylactic machinery. The former—making use, we may take it, of phagocytic action, and where the serum is naturally bactericidal, also of sero-bactericidal action—would deal (according to circumstances more or less effectively) with small bacterial implantations and septicæmic sub-infections. The machinery for epiphylactic defence—making use, as we shall see, of anti-bacterial elements given out by the leucocytes when these are incited by antigen—would deal with larger bacterial implantations and graver blood infections.

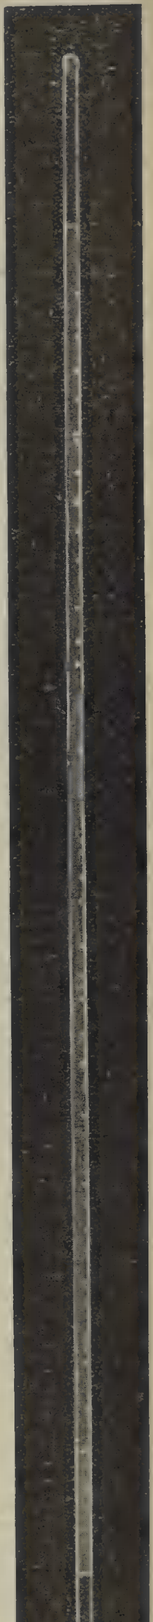


FIG. 3.—Measurement of sero-bactericidal power. Staphylococci implanted into serum growing out into discrete colonies.

---

[3] Wright and Colebrook: Technique of the Teat and Capillary Tube, second edition, Constable, 1921.

[4] The method of culture in capillary tubes was employed nearly 50 years ago by Salomonsen for the isolation of microbes from putrid blood.

Interpreting now in the light furnished by this conception, the results set out in Table I., we see that in this blood the machinery of primary defence is quite singularly inefficient, while that of secondary defence is far more efficient. The blood, implanted with 33 microbes per c.cm., cannot kill one; when implanted with 10,000 per c.cm. it can kill 2000. This increased efficiency plainly indicates that an *epiphylactic response* has been evoked; and whenever we speak of the bactericidal action of the blood we must distinguish sharply between what the blood does where epiphylactic response is evoked and what it does where such a response is not evoked; and we should, when dealing with microbic implantations and infections, distinguish between a sub-vaccinating, a vaccinating, and a critical or optimum vaccinating dose.

TABLE I.

Implantation of graduated dilutions of staphylococcus culture into 40 c.mm. volumes of A. E. W.'s defibrinated blood. The figures represent the number of staphylococcus colonies which developed after 24 hours' incubation in slide cells.

Observer, A. E. W.					Observer, L. C.				
Implantation per c.cm. of blood.	Number of microbes implanted (I.) and colonies found (F.) in 40 c.mm. of blood.		Percentage of survivors.		Implantation per c.cm. of blood.	Number of microbes implanted (I.) and colonies found (F.) in 40 c.mm. of blood.		Percentage of survivors.	
	I.	F.				I.	F.		
8400	336	64	19	21·2	9600	384	74	19	23·7
4200	168	28	17		4800	192	44	23	
2100	84	24	28		2400	96	27	28	
1050	42	7·5	18		1200	48	13	27	
525	21	11·5	55		600	24	15	63	
262	10½	5	50		300	12	6	50	
131	5	5	100		150	6	5	100	
66	3	7			75	3	5		
33	1·5	1·5			38	1·5	2		
—	671	153	22·8		—	766	191	24·9	

It may be added here that precisely similar results are obtained when instead of, as in the tabulated experiments, implanting progressive dilutions of a bacterial suspension into separate samples of blood, we modify the procedure either (*a*) by implanting heavily into a volume of blood and then progressively diluting down this implanted blood with unimplanted, sampling it after each dilution; or (*b*) by making repeated small implantations into one and the same volume of blood, sampling it after each successive implantation.

But to interpret and generalise safely, we must regard not only bloods which have a feeble, but also those which have a powerful machinery of phylactic defence. When we take a blood which has a full complement of leucocytes, and a serum which has an appreciable bactericidal power, and make into this graduated implantations of staphylococcus, quanta up to 1000 and more per c.cm. are killed without residue; and with heavier implantations we have incomplete destruction—with (for this would seem to be the rule) first an increasing, then a diminishing, and after that again an increasing, percentage of survivors. With implantations of 10,000 to 20,000 staphylococci (these would, in case of powerfully bactericidal bloods, seem to be optimum implantations) we may have as few as 1 to 2 per cent. of survivors.

It will, on reflection upon the technical aspect of the question, be realised that with slide cells clear demonstration of epiphylactic response will, in the case of these powerfully bactericidal bloods, be difficult. A preliminary difficulty is created by the circumstance that with the heavier implantations which are here necessary accurate enumeration of the colonies becomes (owing to their crowding) impossible. A second difficulty is created by the fact that when we have instead of a nearly zero base line, a high base line of phylactic power, epiphylactic response can no longer show up clearly. And yet a third difficulty is created by the fact that instead of obtaining, as before, with vaccinating implantations, a bactericidal effect due wholly to epiphylactic response, we obtain, where the primary apparatus of defence is efficient, a result which is due in part to the factor of phylactic and in part to the factor of epiphylactic action.

These difficulties can be diminished by reducing the phagocytic power of these powerfully bactericidal bloods. Instead of working with the normal proportion of serum to corpuscles which obtain in defibrinated blood, we can by diluting down the blood with additional serum, work with an increased proportion of serum and a diminished proportion of leucocytes. Or, again, we can, by incubating our defibrinated blood for half an hour in fine capillary tubes, deplete it of leucocytes. Or finally, by using a combination of these methods we can obtain a blood which is both impoverished in leucocytes and diluted with serum. Such a blood will still, in that its serum exerts a bactericidal action on staphylococcus, differ from a blood of feeble phylactic power. But it will, in despite of that, behave very similarly. Small implantations will no longer be killed off without residue, and we obtain with geometrically diminishing implantations, a characteristically prolonged cauda of survivors.

Fixing our attention upon this cauda, let me explain to you how we can, where we have before us a table which sets out the results obtained from geometrically diminishing implantations of microbes, tell whether epiphylactic response has or has not been evoked. Here I would beg you—for this will greatly facilitate my exposition—to let me call the first figure in any column of implantations or results the *caput*, and all the figures which follow, the *cauda*. You will now on turning to Table I. and looking at the column of implantations see that the number of microbes in the caput must always exceed by a fraction (a fraction which corresponds to the number of dilutions) the total of microbes in the cauda. If now in the column of results we find the number of colonies in the caput sensibly the same as that in the cauda, the conclusion will clearly be that the bactericidal efficiency of the blood does not vary with the magnitude of the implantation. If the colonies in the caput much outnumber those in the cauda, the inference is that the bactericidal efficiency of the blood increases as the implantation is reduced. (Let it be remarked that it would inevitably do so if the serum exerts a bactericidal action.) But if the colonies in the caput are definitely outnumbered by those in the cauda we may—provided always that the microbes in the first blood sample are not so numerous as to interfere with each other's development—confidently conclude that the bactericidal efficacy of the blood increases as the implantation is increased; in other words, that epiphylactic response has been evoked. And by going down the column of results in a methodical manner, comparing the number of colonies in each successive blood sample with the total for the two or three samples next in series, it will be possible to detect the point at which epiphylactic response comes in.

TABLE II.

Experiment showing that when geometrically diminishing numbers of microbes are implanted into a powerfully bactericidal blood, and into the same blood diluted with serum, the serum-diluted bloods give a longer cauda of colonies, and that in the diluted bloods the cauda furnishes more colonies than the caput.

Number of living staphylococci implanted into the 50 c.mm. samples of blood.	Number of colonies of staphylococcus which developed in—			
	Undiluted blood.	Blood diluted—		
		With half its bulk of serum.	With its own bulk of serum.	With double its bulk of serum.
100	1	3	4	3
50	0	1	3 (?)	5
25	0	1	1	5
12	1	0	1	1
6	0	0	0	0

Employing these criteria in connexion with the results obtained from a powerfully bactericidal blood diluted down with serum, we see that evidence of epiphylactic response is here obtained. (Table II.)

Having now seen that bloods of powerful phylactic power when diluted respond after the manner of undiluted bloods of feeble phylactic power to larger bacterial implantations by increased bactericidal action (and all our other methods of testing epiphylactic response will bring confirmation of that) we shall, perhaps, do well before proceeding further to make a general survey of the field of bacterial infections, and see whether the doctrine of phylactic and epiphylactic defence enumerated above accords with the events which come every day under clinical observation.

Three types of cases should be called to mind :—

1. The type of infection (exemplified by streptococcic endocarditis) with for a long time only very few microbes in the blood, with only moderate pyrexia, comparatively little constitutional disturbance, and a protracted and almost always fatal course. These cases would well be explained by assuming that the machinery of first defence has failed to do its office and that the epiphylactic machinery has never been called into action.

2. The type of case (exemplified by croupous pneumonia) with from the outset an intense infection, high temperature, and heavy bacterial intoxication, and a course which very rapidly terminates either in death or in recovery by crisis. The cases which recover would be well explained by assuming that the epiphylactic machinery is here effectively, though tardily, brought into operation; those cases which terminate fatally, by supposing the epiphylactic machinery to have been put out of action by overwhelming bacterial intoxication.

3. The type of infection where we have either a regular hectic temperature, as in phthisis and locked-up suppuration, or else such steep ascents and descents of temperature as accompany the rigors of acute streptococcus septicæmias. Here we may assume—and such opsonic and bactericidal observations as are to hand are in accord with this—that whenever bacterial poisons in sufficiency are conveyed into, or as the case may be, generated in the blood, the machinery of epiphylactic defence is, with results that are for the immediate moment satisfactory, called into action.

When once we survey the phenomena of infection from the point of outlook here suggested, the question arises in the mind whether in all these cases it might not be possible to bring the machinery of epiphylactic defence into effective operation by a direct introduction of vaccine into the blood. The proper dose to inoculate here would, of course, be that quantum (I might, perhaps, call it the critical dose) which would, taken together with the bacterial elements already in circulation, evoke in the patient's blood a maximum response. If the epiphylactic response to infection could in this way be expedited and reinforced, three advantages would be gained. First, the poisoning of the leucocytes—poisoning which upsets the machinery of both phagocytic and epiphylactic defence—would be avoided. Secondly, the patient would be spared that intense systematic poisoning which may bring him near to death before the life and death struggle with his infection even begins. And thirdly, the patient would be spared all that grave damage which is inflicted on his tissues at the site of infection.

Implantations of Dead and Living Microbes into the Blood in Vitro.

Inculturing Experiments.—Coming back to our experiments, we may consider next the effect of introducing into the blood instead of only living microbes a proportion of dead and a proportion of living microbes: (1) The dead may be implanted into the blood first and afterwards the living. That will be comparable to prophylactic inoculation undertaken with a vaccine of dead microbes, and followed by either a test implantation of living microbes or exposure to infection. (2) Or again the dead and the living microbes may be implanted into the blood simultaneously. (3) Or lastly—and this will be analogous to inoculation in the incubation period and to vaccine-therapy—the living microbes may be implanted first and afterwards the dead.

Let me put off for a moment telling you of the results obtained. For we must first clarify our ideas and see whether there is really a definite line of division between vaccinating and assaying, and ask ourselves whether we have a perfectly clear idea as to what we mean by a vaccinating and an assaying or test dose. These will probably seem to you to be perfectly idle questionings, and you will, perhaps, think that they could be settled straight off, by defining the *vaccinating dose* as that which comes first in order of time, which evokes the epiphylactic response, and which normally consists of dead microbes; and the *assaying dose* as that which follows after, which consists of living microbes, and which finds out what epiphylactic effect has been obtained. In reality, however, these definitions do not go down to the root of things, and they regard only prophylactic immunisation.

When we pass to the case of inoculation in the incubation period and to vaccine-therapy, the terms vaccinating dose and test dose must, it will be allowed, be interpreted somewhat differently. The living microbes which have effected a lodgment in the body here officiate as the test dose, and the dead microbes which are subsequently inoculated, as the vaccinating dose. But here it may still be maintained that vaccinating and assaying are operations apart, and that here only the order of the doses has been changed. When, however, we come to the experiments in which an epiphylactic response is evoked by importing living microbes into the blood, it becomes plain that the distinction between vaccinating and assaying can no longer be sustained. For we have here not two separate and independent operations, but a single and indivisible vaccinating and assaying operation. And, of course, the same holds good of septicæmic infections. There the infecting microbes are the agents which produce, as the case may be, epi- or, as the case may be, apo-phylactic response, and they officiate at the same time as indicators of the changes effected.

There is still, in connexion with this subject, one further point that requires to be considered, and it is one which has already been adverted to. We saw in connexion with the discussion of dead and living vaccines that it is not the dead or living microbes as such, but soluble elements extracted from the bacteria which officiate as the antigen, and we further saw that such soluble elements are extracted irrespectively of the bacteria being living or dead. It follows that where (1) dead and living bacteria are implanted simultaneously or in succession into the blood, or (2) living microbes (in the form of abortive infections or test doses) are introduced into an organism already vaccinated, or (3) dead microbes are inoculated into an already infected organism, all the microbes, irrespectively of their being dead or alive, will make their contribution to the final result. And especially in connexion with therapeutic inoculation it will be important to observe that the really operative dose—the dose which, as the case may be, produces an epiphylactic or apophylactic effect—will in each case be the amount of antigen introduced in the vaccine, supplemented by that contributed by the infecting microbes.

This is the rationale of well-established rules—of the rule that in prophylactic operations we may, because here the active principle supplied from without will not be supplemented from within, employ a considerable dose of vaccine; and of the rule of therapeutic inoculation, that we must carefully consider the volume of infection, so as to introduce, as a larger quotum is supplied from within, a smaller quotum in the form of vaccine; and again of the rule that we should abstain from inoculation where a hypervaccinating dose is already circulating in the blood.

But though it is important to realise that when it is merely a question of furnishing antigen, dead microbes can take the place of living and vice versa, we must not allow ourselves to forget that, except only in the matter of furnishing antigens, the dead microbes which are introduced in vaccines stand on an absolutely different footing to the living microbes which produce the infection. The principles are in reality very simple. The dead microbes provide our therapeutic agent, but the living decide the issue. Upon the doses of vaccine administered will depend the magnitude of the vaccinating response, but the effectiveness of that response will, both in prophylactic and therapeutic procedures, depend upon the number of living microbes that have to be dealt with. We shall see that precisely the same holds also in vitro. It is essential to regulate the total of antigen which is brought into operation. But more important still is it to keep within certain limits the number of living microbes we implant in the assaying dose.

Three other points in connexion with experiments in which dead and living microbes are implanted into blood must also be kept in mind in connexion with every one of the experiments which I have cited and am about to cite. The *first* is that in what are designated living cultures there is always a variable and therefore unknown proportion of dead microbes. The *second* is that from the point of view of the evocation of physiological effects we must not range in the same category of efficacy all kinds of dead microbes or, as the case may be, all sorts of living microbes. To take the case of dead microbes, some like typhoid bacilli which have been killed at 56° C. readily dissolve in serum, and to a less extent in watery media. Others like typhoid bacilli, which have been heated above 72° C., are comparatively insoluble, and furnish vaccinating elements which are not only less in quantity, but also presumably less efficacious. And the *third* point to be borne in mind is that in vaccinating we are dealing, not as in ordinary chemical operations with reagents which are fully dissolved, but with substances which may sometimes fail to pass into solution, and may at other times pass into solution very slowly. It is in conformity with this that a dose of vaccine should sometimes give a blank result, and at other times, especially when inoculated intravenously, first a positive and afterwards a negative phase. Let me now show you the results of some experiments in which dead and living microbes were implanted into defibrinated blood in vitro.

EXPERIMENTS SHOWING THAT INCREASED HÆMO-BACTERICIDAL EFFECT IS OBTAINED BY VACCINATING BLOOD IN VITRO.

Below are subjoined first the result of two experiments conducted on my own blood.

Effect of Implanting Dead and Living Microbes into Blood.

Here the dead and living of microbes were implanted simultaneously into 25 c.mm. volumes of blood and the implanted blood was afterwards filled into and incubated in fine capillary tubes.

Experiment 1.

Test dose.*	Vaccinating dose.†	Aggregated implantation.	Negative or positive result of culture.
Living staph. per c.cm. Circ. 2,000	Dead staph. per c.cm. 32,000	34,000	+
,,	,,	,,	+
,,	16,000	18,000	+
,,	,,	,,	+
,,	8,000	10,000	+
,,	,,	,,	+
,,	5,000	7,000	0
,,	,,	,,	0
,,	4,000	6,000	+
,,	,,	,,	+
,,	2,000	4,000	+
,,	,,	,,	+
,,	Nil	2,000	+
,,	,,	,,	+
,,	,,	,,	+

Staph. = staphylococci.

* 1 wash of a dilute suspension of living staphylococcus.

† 1 wash or a multiple or submultiple of a sterilised 8-fold stronger staphylococcus suspension.

Details of the Bacterial Enumerations upon which the Figures in the Above Table are Based.—The staphylococcus suspension which furnished the test doses was further diluted 10-fold, and of this a wash or a submultiple of a wash was implanted and incultured in 25 c.mm. volumes of my serum.

1 wash gave 5 colonies.
1 ,, ,, 5 ,,
$\frac{1}{2}$,, ,, 3 ,,
$\frac{1}{4}$,, ,, 1 colony.

There being thus in 1 wash of the diluted culture used for this enumeration an average of 5 microbes, there would be in 1 wash of the suspension which furnished the test dose 50 microbes. And this (seeing that 25 c.mm. of blood were in each case employed) works out as an implantation of 2000 (50 × 40) staphylococci per c.cm.

Experiment 2.

Here a precisely similar technique was employed.

Test dose.	Vaccinating dose.	Aggregate implantation per c.cm.	Number of survivors per c.cm.
Living staph. per c.cm. 1,200	Dead staph. per c.cm. 12,000	13,200	363
,,	,,	,,	
,,	6,000	7,200	48
,,	,,	,,	
,,	4,000	5,200	180
,,	,,	,,	
,,	3,000	4,200	462
,,	,,	,,	
,,	Nil.	1,200	200
,,	,,	,,	
,,	,,	,,	

Experiment 3 shows a quite dramatic result obtained with a blood which was *ab origine* one of great bactericidal power.

Experiment 3.

Here the vaccine of dead staphylococci was implanted in vitro into defibrinated blood. The vaccinated blood was kept on the bench and then after three-quarters of an hour graduated dilutions of living staphylococci were implanted—the volume of staphylococcus suspension being always 2·5 c.mm. in 50 c.mm. of blood. After implantation the blood was filled into slide cells and incubated.

Variety of blood into which living microbes were implanted.	Number of microbes per cent. which developed from an implantation of—							
	20,000	10,000	5,000	2,500	1,250	600	300	150
	living staph. per c.cm.							
Unvaccinated blood	7·4	5·2	6	5	16	6·6	0	0
Blood vaccinated with— 12,000 staph. per c.cm. ..	1·5	1·4	0·8	1·6	1·6	3·2	0	0
6,000 dead staph. per c.cm. ..	0·6	0·4	0 8	0·0	1·6	3·3	7	0
3,000 dead staph. per c.cm. ..	6·1	1·6	5·2	8	1·6	3·2	0	0
1,500 dead staph. per c.cm.	5	5·4	5·6	6	1·6	3·2	0	0

Details of the Bacterial Enumeration upon which the Figures in the Table are Founded.—Here in each case 2·5 c.mm. of the 32-, 64-, and 128-fold dilution of the bacterial suspension used for the strongest implantation was incorporated into 50 c.mm. of serum, and then incultured. The number of colonies which developed in the serum implanted with the 32-, 64-, and 128-fold dilutions were respectively (the counting operations being conducted in duplicate) 31 and 30, 18 and 19, and 6 and 7. This (taking the first figures) works out as (30 × 20) an implantation of approximately 600 living staphylococci per c.cm. in column 6 of the table.

Attention may here be directed to three points :—

1. All the vaccinated bloods kill here all along the line more microbes than the unvaccinated blood, the best results being in this particular case obtained with blood vaccinated with 6000 dead staphylococci. This blood in the case where 20,000 living staphylococci were implanted killed off per c.cm. 1360 more staphylo-

cocci than the unvaccinated blood; and it killed off without residue 2500 as compared with 300 staphylococci.

2. The second point is one of general theoretical importance. When comparable numbers of microbes are employed, these being, in the one case, all derived from a living culture, and, in the other case, in part from a living and in part from a sterilised culture, better results are in every case obtained with the blend. Thus, for example, we have in column 1 with an aggregate implantation of 20,000 living staphylococci a percentage survival of 7·4, and in column 2 with an aggregate implantation of 22,000 staphylococci, consisting of 12,000 dead and 10,000 living, a percentage survival of 1·4; and again, we have in column 2, with an aggregate implantation of 10,000 staphylococci a percentage survival of 5·2, and in column 3, with an aggregate of 11,000 staphylococci, consisting of 6000 dead and 5000 living, a percentage survival of 0·8. It would thus seem—but one must be cautious in inference, because there are no cultures which contain only living microbes—that dead microbes are, micro-organism for micro-organism, more efficacious than living; and that vaccines of sterilised cultures should be preferred to living vaccines, not only because their use is unassociated with risk of infection, but also because they are superior in quality.

3. The third point is also of fundamental interest. And it is a point that has already been considered. When in our assaying operations we introduce microbes into the whole blood or into a serum or pus fluid which contains leucocytes, or even, as in the opsonic technique, into an artificial mixture of washed leucocytes and serum, the microbes we implant may, despite of our having implanted them solely for the purpose of testing, evoke (this will depend on their number) a secondary epiphylactic response which will give increased anti-bacterial power such as is presumably achieved when slighter infections supervene upon a prophylactic procedure. Or again, the microbes we implant for the purpose of testing may, like really graver infections supervening upon a prophylactic procedure, get the better of the blood resistance, and eat up, or more than eat up, the surplus of anti-bacterial power furnished by the original vaccinating operation. It will, in view of these superadded effects, be very difficult to assess the actual achievement of the prior vaccinating operation. Apparently the best that can be done in the way of assessment will be to get the leucocytes out of the way before we undertake our tests, and content ourselves with measuring the bactericidal and opsonising power of the serum. Consideration of the effect produced by the intravenous inoculation of vaccines upon the hæmobactericidal power may with advantage be postponed until the argument of this lecture has been a little further developed.

IMPLANTING AND EXPLANTING EXPERIMENTS.

Up to the present we have been studying the results obtained by implanting living microbes separately or associated with dead microbes into the blood and inculturing. This method measures the destructive power of leucocytes and blood fluids operating in conjunction. But while it tells us what number of microbes are killed it tells us nothing about the pace of destruction, and nothing even indirectly about the agency by which the microbes are destroyed. And again the inculturing method has a definitely limited range of utility. For when over, let us say, 60 colonies develop in 50 c.mm. of blood accurate enumeration begins to become difficult. The implanting and explanting method supplies what is wanted in these respects. It will be proper first of all to satisfy ourselves that the general results obtained by this method are conformable to those obtained by inculturing. And, inasmuch as we are here specially concerned with the verification of the proposition that epiphylactic response can be evoked in the blood in vitro, and is evoked only when we implant sufficiently heavily, it will be well to first study my blood whose feeble phylactic power makes it specially well adapted for the institution of experiments on epiphylactic response.

In these implanting and explanting experiments implantations of 2·5 c.mm. volumes of graduated dilutions of a suspension of living staphylococci were made into 50 c.mm. volumes of A. E. W.'s defibrinated blood. Then samples were taken from each implanted blood, and these were first diluted 25-fold and then spread out over the surface of agar plates. The first samples were explanted instantaneously—instantaneously being here understood to mean instantaneously after the blood and microbes had been duly mixed—and the other samples after longer intervals. The implanted bloods were in each case kept not in the incubator but at the temperature of the air.

Experiment A.

Blood vol.	Number of living staphylococci implanted— per c.cm. of blood.	per 2 c.mm. of blood.	Number of colonies which developed from that volume explanted after the stated interval. 0′	30′	60′	120′	Number of staphylococci implanted into the samples.		Number of colonies which developed out of those samples.	
1	16,500	33	26	20	27	23	132	264	96	148
2	11,000	22	12	6	11	—	66		29	
3	5,500	11	8	2	3	5	44		18	
4	2,750	5.5	2	1	1	1	22		5	
5	920	1·9	1	2	2	1·5	7·6	11·65	6·5	10
6	460	·9	1	0·5	0	1·5	3·6		3	
7	230	·45	0	0	0	0·5	·45		0·5	

Experiment B. (The same technique was employed.)

Blood vol.	Number of living staphylococci implanted per c.cm. of blood.	Bactericidal effect in sample explanted immediately.	Bactericidal effect in the four samples explanted within three hours.			
1	12,000	22 reduced to 8	90	184 reduced to	15	42
2	8,000	15 ,, 10	60		15	
3	4,000	7·5 ,, 0	22·5		5	
4	2,000	3·75 becomes 5	11·5		7	
5	800	2·25 ,, 2	7·75	14·5 becomes	8	16
6	546	1·5 ,, 2	4·5		5	
7	270	0·75 ,, 0	2·25		3	

Experiment C. (Again the same technique is employed.)

1	5,400	10·8 reduced to 5	43	57·5 reduced to	18	25
2	1,800	3·6 ,, 1	14·5		7	
3	360	0·75 becomes 1	3	4 becomes	3	3
4	170	0·25 ,, 0	1		0	

It will be seen that the conclusions which were reached by the inculturing method are here all confirmed. We again arrive at the result that the particular type of blood here in question exerts no bactericidal effect when only small numbers of staphylococci (1000 per c.cm. and fewer) are implanted, and that it exerts a very conspicuous effect when larger numbers of staphylococci are introduced. In the three experiments here set out there is with the smaller implantations no killing whatever, and with the larger implantations an average killing of 60 per cent.

Experiment D.

Here 7·5 c.mm. of an enumerated staphylococcus culture was implanted into 300 c.mm. of A. E. W.'s defibrinated blood and immediately afterwards a 30 c.mm. sample was explanted on to an agar plate. That done another 7·5 c.mm. of the staphylococcus suspension was implanted, and immediately another 30 c.mm. sample was explanted—the same procedure being followed throughout.

Number of staphylococci implanted per c.cm. of blood.	Number implanted in the 30 c.mm. of blood used for explantation.	Number of colonies which developed from that 30 c.mm. of blood.	Percentage of survivors.
400	12	11	99
840	25	10	40
1,310	40	—	—
1,850	56	18	32
2,450	75	26	34
3,125	100	17	17
4,625	140	48	29
6,300	190	69	31
8,150	245	108	44
10,250	310	148	48

The figures for the implantations were obtained by enumerating the staphylococcus suspension in 50 c.mm. volumes of serum. An implantation of 2·5 c.mm. gave 44 colonies, one of 7·5 c.mm. 140 colonies, and one of 10 c.mm. 135 colonies, giving a total of 319 colonies in the 20 c.mm. of suspension implanted. This works out as 16 staphylococci in 1 c.mm., and 12 in 0·75 c.mm., the volume of the bacterial suspension in the 30 c.mm. of blood used for the first explantation.

Further, these experiments bring out—and this is their new contribution—that of the total of microbes killed by the blood the larger proportion (here two-thirds of those killed) are killed instantaneously.

Let me in connexion with this make clear the following points: (1) Subitaneous killing of microbes is obtained practically invariably. Where it fails to occur that may perhaps depend upon the antigen not being brought into solution. (2) The fact that microbes can be killed instantaneously by the evoking of epiphylactic response has, as we shall presently see, very important practical applications in connexion with the treatment of bacterial disease. (3) The fact that microbes are killed instantaneously and at ordinary temperatures throws important light on the mode of bacterial destruction and on the nature of epiphylactic response. If we had had to depend here only upon the inculturing method we might perhaps have supposed that the implanting of a sufficient quantum of microbes led to an activation of the machinery of phagocytosis. But when we learn, as we do from these experiments, that microbes are killed instantaneously at temperatures at which phagocytosis begins only after very appreciable delay, we are compelled to conclude that subitaneous killing cannot be due to phagocytosis. It must therefore perforce be attributed to a bactericidal action of the serum.

The generalisation that subitaneous killing of microbes in the blood is due to a bactericidal action exerted by the serum furnishes in its turn a new articulating point upon which a further framework of generalisations can be assembled. From the fact that the blood can kill microbes instantaneously it can be inferred that a bactericidal serum also must be competent to kill instantaneously. Further, when we have realised that the serum receives, when we vaccinate the blood, a quite sudden access of bactericidal power, and when we reflect that where massed leucocytes washed free from serum are imposed upon agar implanted with staphylococci or streptococci, these[5] last are killed extracellularly and by chemical agency, we are almost inevitably conducted to the conclusion that the bactericidal elements found in vaccinated bloods are derived from the leucocytes, and that leucocytes can, under the influence of a vaccinating dose of microbes, instantaneously export their antibacterial elements into the surrounding blood fluids.

We shall, as we proceed, see all of these inductions confirmed by actual experiment. But here another issue must take precedence. I have already elsewhere[6] shown that when epiphylactic response is evoked by adding vaccine to blood the serum becomes bactericidal, or as the case may be, more bactericidal, not only to the species of microbe which has furnished the vaccine, but also to many non-homologous microbes. This does not stand by itself. It would seem that all the antibacterial elements that are brought forth in the blood—and it will presently appear that opsonic substances also are generated—are polytropic.

It is unnecessary to say much in the way of general comment on the fact that the antibacterial substances here in question are polytropic. For while established notions prejudice us against the idea of vaccination conferring a non-specific protection, reflection puts out of court all alternative suggestions. In the first place, where the blood kills microbes instantaneously there is time for delivery but not for manufacture of anti-bacterial elements. And again, it is much more difficult to conceive that the leucocytes should have stored up in their protoplasm special monotropic bactericidal substances and opsonins for each and every description of microbe than to conceive of the leucocytes being furnished with a common store of polytropic antibacterial elements which could be brought into operation upon all microbic invaders without distinction of species.

And in this connexion something further may be added. When once we have pictured to ourselves that non-specific anti-bacterial substances can, under the stimulus of any antigen, be exported from leucocytes, it does not perhaps involve a much more adventurous flight of imagination to conceive that an effective vaccinating stimulus might be supplied to the leucocyte by chemical agents other than bacterial antigens. Certain clinical and also some experimentally established facts would very well harmonise with such a conception. Here would come the fact that emetin, though not directly nocuous to the *Amœba histolytica*, can rid the intestine of that infection. To this might be added the fact that salvarsan can in syphilis, complicated with a heavy streptococcic infection, very rapidly rid the body of the latter—a fact which should be brought into the same visual field with the observations of S. R. Douglas and L. Colebrook, which establish that after salvarsan and neosalvarsan injections the blood becomes for a period of a few hours bactericidal to streptococcus and staphylococcus. And again, there might be added the observations of Walbum,[7] which show that the yield of diphtheria antitoxin and of agglutinins to the *Bacillus coli* can be very appreciably increased by the exhibition of manganese chloride and other metallic salts.

(*To be continued.*)

THE CLINICAL RESULTS OF THE TREATMENT OF MALIGNANT DISEASE BY X RAYS.*

BY J. H. DOUGLAS WEBSTER, M.D.,
M.R.C.P. EDIN.,
PHYSICIAN-IN-CHARGE OF THE DEPARTMENT OF RADIOLOGY,
MIDDLESEX HOSPITAL, LONDON.

WITH reference to the value of statistics Mr. James Berry, in his recent address on the Progress of Surgery, said: "We sometimes hear of the mortality of such and such an operation. There is no such thing. The mortality depends on the condition for which it is done, upon who does it, and when it is done." Much the same may be said of X ray treatment and its results. The aim of radiation treatment in different cases may be prophylactic, or palliative, or curative, and the results of each should form a separate statistical group. Cases treated by prophylactic radiation in collaboration with the surgeon should certainly form a separate group, subdivided according as the radiation is given before the operation or after, or both. The results of palliative radiation after many incomplete operations or in inoperable cases (and, perhaps, the majority of cases at present referred to the radiologist are in this group) should be considered apart. In only a small proportion of the cases referred to us can we make an attempt to arrive at a definite cure.

Superficial Basal-Celled Epitheliomata.

In this third division (curative aim) the majority of cases are those with superficial epitheliomata of the "basal-celled" type. Here, as in malignant disease elsewhere, if a wide enough area be removed or destroyed, by excision or curette and caustics, the result in a very large percentage of cases will be cure.

[6] Wright: Lessons of the War, THE LANCET, March 29th, 1919.

[7] Communications de l'Institut Séro-thérapique de l'État Danois, tome xii., 1922.

* Based on a contribution to a discussion on the subject at the Medical Society of London, Jan. 22nd, 1923.

But in rodent ulcer excision is often not wide enough for cosmetic reasons, thus in a number of supposedly successful excisions McKee has cut serial sections of the whole excised tissue, and found that the disease extended right to the margin of the incision. He suggests that such an examination might be done in all surgical cases, and radiation applied afterwards if indicated. The results with X rays or radium (McKee regards these agents here as of equal value) give better cosmetic results than do surgical measures, and the percentages of clinical cure are as high or higher; McKee out of 644 cases reporting 91 per cent. cure, Wetterer 96·2 per cent. out of 852 cases. Meyer 99 per cent. without recurrence. McKee usefully analyses his causes of failure, which are worth consideration, as they also apply to X ray work in other areas. Apart from non-attendance of the patient for further treatment, or very advanced and practically hopeless condition on commencing treatment, his chief causes of failure were technical—i.e., failure to give sufficient radiation to the deeper strata of cells so that recurrence took place in the depth, or failure to radiate a wide enough area beyond the visible and palpable extent of the lesion. The latter must be a common source of imperfect results in deep-lying growths, of whose extent we must often remain ignorant by clinical means. Stiles and Handley have shown the very wide extent of breast invasion, and many other apparently localised deep malignant lesions must also extend widely. Failure is sometimes due to marked resistance to radiation, but this is most usually observed when long-continued fractional doses of radiation have been given. This fact was recognised as far back as 1904 by Kienböck and Belot, who even then favoured "intensive" methods, and its importance has recently been specially emphasised by Regaud, who has shown how prolonged fractional methods of treatment produce in the successive generations of malignant cells an "auto-vaccination" against radiation. Regaud says: "The conception of the more or less rapidly weakening efficacy of successive treatments is fundamental; it should dominate the radiotherapy of cancer." Inadequate or wrong method of dosage, then, in some way or another, McKee finds the chief cause of failure. Finally, he points out that inadequate observation of cases is a frequent cause of failure, and advises that after an apparent clinical cure the patient should report for an examination every six months for five years; only in this way can recurrences be checked in time.

Squamous-Celled Epitheliomata.

The results in squamous-celled epitheliomata are not as good as those already quoted, owing to the frequent early wide invasion, and the primary is a more resistant type, more intense doses being needed, Bordier recommending up to 26 H. in single doses. Brock has reported excellent results with doses not quite so large as this. Of 68 inoperable face cases Wetterer had clinical cure in 34, of 34 lower-lip cases a clinical cure of 25 (73 per cent). Shepherd, using Broders' histological classification, has grouped the results of lip cases into four series as regards malignancy. When the cells are most differentiated the results of surgery or radiation are excellent. In the 1 or 2 per cent. where undifferentiated cells predominate the results appear to be uniformly bad. Regaud reviews the lip cases treated with X rays and radium; with the latter Forssell reports cure of 20 early cases out of 34, and Regaud reports satisfactory results, up to the present, in 16 cases out of 22.

Pancoast has had good results in lip cases with radiation alone. As regards prophylactic work he says:—

> "It is our firm belief that every case should have at least a preliminary application of radiation before any attempt at removal of the primary lesion or glands is attempted." He has "practically discontinued giving post-operative radiation unless it is employed as an ante-operative measure as well." "It is a well-recognised fact," he says, "that radiation cannot do well in what surgery has tried to do and failed. The recurrent case after operation does not respond as well as the primary case, because we have to deal with anatomical, physical, and biological factors that are quite different. . . . Cancer tissue once directly traumatised by surgery, without a complete removal, and without previous radiation, does not respond well to any form of treatment."

With our present knowledge this conclusion cannot be applied to all sites of the body, many results, indeed, contradict it; but it may be true of lip cases. In early or moderately advanced cases Pancoast recommends radiation alone, or diathermy and radiation, or a preliminary radiation followed by excision and block dissection and further radiation—a combined X ray and radium technique being frequently used.

The tongue is a most unfavourable site for any form of treatment, but clinical cures by radiation are recorded, especially by methods of radium implantation. With X rays cases often fail to react with massive doses, and do better with repeated fractional doses, given within a period of a month or two at most, as the good radium results of Regaud and others would suggest. Baensch has noted the advisability of some form of fractional dosage in floor of the mouth cases, and my observations tend to confirm this. A few primary upper laryngeal cases have been reported to have done well, also recurrences after laryngo-fissure. Some of my post-operative cases have shown disappearance of grey patches, and clinically slight recurrences.

Treatment of Breast Cancer.

The breast is one of the most difficult areas to treat, both for the surgeon and the radiologist. There are so many factors involved, and each factor is of such importance, that most published statistics leave much to be desired. From the pathological standpoint very dissimilar breast tumours are commonly grouped together for statistical purposes, which Ewing has justly described as a fallacy. From the clinical standpoint cases should be grouped in grades according to extent of invasion (Steinthal's or other group-scheme). For the chance of cure is remote if the supraclavicular glands are once reached; if there are palpable axillary nodes the chance of cure by operation is about 1 to 25 (Ewing), and the general results of operation are clinical cure of 20–40 per cent. Of cases coming to the surgeon already about 25 per cent. are inoperable. The breast, therefore, is one of the fields where radiology may be expected to be of the greatest service in an attempt to reduce the mortality below 70 or 80 per cent. (the percentage of those who would otherwise die of the disease) or in prolonging life beyond the 2½–3½ years' average duration. As elsewhere the radiation results should be considered as prophylactic, palliative, or curative. The best results published so far appear to be those of surgery and radiology combined—for example, those of Anschütz, in a series of 240 cases, with 77 per cent. free of recurrences in 1–3 years, 60 per cent. free at 3 years, and cure of every case of local recurrence. The value of prophylactic radiation in breast cases has been much discussed lately.† But of the widely quoted statistics of Naher, in Perthes' clinic, which started the discussion, it was well said that "no cautious statistician would draw any important inference therefrom."‡ Essential details, such as the patient's age, type of growth, &c., and time and exact method of applying the radiation, are not given. The latter details are vitally important. Blumenthal found that most cases were referred to him for radiation two or three months after the operation, which is much too late. In some cases supra- or infra-clavicular glands had already appeared, so that, as he says, it was no longer "prophylaxis." He and several others attribute bad results to faulty method or technique. The chief cause for failure with rodent ulcers has been attributed to wrong technique, and it must be the same with a considerable proportion of failures in breast work. (A remote factor, Strauss notes, is the extraordinary differences in cancer death-rates in different parts of Germany in 1918–19; these varied, approximately, from 21·5 per cent. in

---

Frankfort and Munich to 60–69 per cent. in Berlin, Leipzig, and Hamburg.) The method of uniform radiation of a large surface (plane, convex, &c.) was fully discussed so long ago by Holzknecht that it is almost incredible that patients have been observed with lines of recurrences between two limited fields of application (Halberstädter, Blumenthal, and Jüngling have all recorded such clinical observations on cases radiated elsewhere). By a near method, or a distant method like Wintz's, or Holfelder's with one or two tubes at a time, it is possible to give an even surface radiation. Methods can be tested by Kienböck strips or Jüngling's bean method, on patients of different configuration. The pleural dose is another matter, however, as full doses cannot be given at this depth without skin damage (unless in very thin patients). Hence in this region it is necessary to repeat radiation at intervals of 2 to 4 weeks, and again at monthly or longer intervals. By this method a cumulative effect is hoped for on any deeper invasions without producing skin damage. The doses advisable vary, many give too large doses, as Strauss points out; in true "prophylactic" work, after operation on a grade 1 case, only what may be called pre-cancerous or latent cancer cells are left to be dealt with, and these young cells are markedly radio-sensitive. Repeated two-third skin doses should here suffice. It is quite otherwise with advanced grade 2 cases; here in any one of the efferent breast lymphatics left behind after operation, in the supraclavicular triangle, axilla, thoracic wall, anterior mediastinum, or epigastrium, there are probably microscopic channels blocked with mature cancer cells, and in inoperable grade 3 cases this extension is certain in one or more directions. (Pfahler, indeed, finds radiographic evidence of mediastinal or lung involvement in half the cases which come to him.) In these cases one or two massive applications would seem to be preferable if the patient's condition permits of an intensive method. The results of imperfect technique in breast work have been clearly pointed out by Wieser, who gives the pathological findings in a case referred to him by Lorenz. It was a case with a very large inoperable tumour which became so reduced in size a fortnight after radiation that it was removed by Lorenz a month after the treatment. The tumour cells were found to be necrosed with the exception of two deeper layers which had had insufficient radiation. The great importance of avoiding as far as possible plus- and minus-zones of radiation is emphasised by Wieser; the minus-zones do not damage the cancer cells enough, and in them recurrences may take place (as in the strips between limited fields); plus-zones damage the connective tissue, an essential factor in the regression of some types of tumour (in areas badly damaged by excessive radiation recurrences have been seen which no further radiation could affect). Wieser considers that the combination of plus- and minus-zones can very easily lead to distant metastases; it will certainly promote neither the resolution of lines of lymphatic invasion nor the immunity induced by the absorption of radiated and degenerating tumour cells (by "cell-decay hormones," as Freund described them) which is an experimentally well-founded and clinically very probably an important factor in the benefit produced in many cases by radiation. After post-operative radiation Handley says that in his series of cases recurrence in the skin was practically never seen. In three of the five cases in which it occurred the usual prophylactic X ray course had somehow not been given. Out of about 150 breast cases radiated in the past year I have seen very few recurrences while a course of X rays was in progress; a considerable number coming for treatment have shown regression, at least temporarily. About five cases of recurrence in bone have been treated with inconclusive results so far; Holfelder claims to have good results in such cases.

Pre-operative radiation in breast cases is now very largely advocated, especially in America, to prevent local implantations and dissemination during operation (the possibility of this, especially in sarcoma, has long been recognised, and dissemination has taken place in animal tumours as a result of massage of the growth). Sittenfeld reports very good results (not detailed) with 65 cases who had intensive radiation before and after operation.

Curative Radiation of Primary Cases.

For curative radiation of primary cases the best chance is in the early soft medullary type, according to Wetterer and Rieder. Cases of this sort are rare, and rarely seen by the radiologist. Some hold that the end-results with scirrhus are better. Rieder recommends centripetal radiation; the most dangerous part is not the tumour, but the growing edge, which should be attacked first.

On grounds like those of Pancoast with lip cases, that scar tissue and the operative damage to lymphatics make areas operated on unfavourable for radiation, Wintz holds that all operable breast cases should be radiated and not operated on. The results in his radiated cases will be of interest, but the primary mortality is so slight that there is not the same occasion for preferring radiation to operation as Krönig claimed to have in uterine cases, when he abandoned operation in uterine cancer. And certainly large breast tumours, at least, are much better removed by operation or diathermy when possible, so that radiation of the deeper chest wall sufficient to prevent recurrence can be applied with certainty. I have had two operable primary breasts in which the growth practically disappeared, one treated with X rays, the other with radium. In one case operation was refused, in the other the general condition made operation inadvisable. Palliative radiation offers a wide field, sometimes resulting in operability, or else relief from pain, ulceration, &c., or delaying the further extensions, and the almost inevitable issue. I have found in ulcerated cases the best results when zinc or other ionisation has preceded the radiation.

Growths of Mediastinum, Testicle, and Prostate.

In mediastinal growths a few clinical cures have been reported, and a large proportion of cases show temporary benefit. I have had seven cases in the last year. Where the hilum glands are involved care must be taken not to produce too rapid a reaction. One case (Hodgkin's disease) is reported by Czepa; there the patient died a few hours after the radiation owing to local œdema and tracheal pressure. Some form of fractional dosage is therefore advisable, to begin with at least. Testicular tumours are of great interest. I have five cases at present under observation for lumbar gland extension or for recurrence after testicular removal, several responding satisfactorily. Béclère has reported cases from time to time, and lately has collected 11 cases of his own and others in which the abdominal tumour was very radio-sensitive; the primary growth in each case was the testicular "carcinoma," a seminoma. Even desperate cases, with cachexia, and very large secondary tumour, or with distant metastases, have recovered. Of the cases reporting for prostatic malignancy at the Mayo Clinic, Bumpus has reported that 28 per cent. already show bony metastasis. This is a much larger percentage than is elsewhere reported, but at the Mayo Clinic every case is thoroughly examined radiographically. Barringer in a series of cases found that in only 2 per cent. was the disease confined to the prostate; in most cases there were already extensions to the vesicles, the bladder, the lateral pelvic walls, or distant metastasis. These findings make the outlook very unfavourable for any form of treatment. Radium implantation methods for prostatic malignancy have been developed in some American centres. At the Mayo Clinic the process is to bury radium first and then enucleate if possible. Cases referred to me have already been far advanced.

Gynæcological Conditions.

In malignant gynæcological conditions there is a wide range of opinion and practice at present as to the value of operation or radiation. At Munich, Erlangen, Freiburg, Heidelberg, and Frankfort, in the gynæcological clinics, no case of uterine cancer has been operated on for several years. In operable cases the primary and end-results of radiation are considered better than with operation, and a small percentage of inoperable cases can be cured by radiation. 30 to 50 per cent. of all cases are inoperable; a determined effort has to be made to deal with them, and this fact, with a very high primary death-rate after Wertheim operations, led Krönig to initiate the present extensive trial of radiation alone. An analysis by Berger of Krönig's cases of the years 1913–16, when the intensive X ray technique was being developed, shows that even the late radiation results of mixed operable and inoperable cases are slightly better than the operative results. With improved technique the difference may be expected to become more marked. Time has not yet elapsed for the early result of 97 per cent. clinical cure from Erlangen in 24 operable and inoperable cervical cases to be confirmed by five years' observation; over 50 per cent. are said by Seitz to be well two years after the X ray treatment.

There is already a large literature comparing the results with radium as opposed to operation in cervical cancer; at five years Kehrer had 45·4 per cent. recurrence-free with radium, at three years 54 per cent., at five years Döderlein had 80 per cent., and Heymann at Stockholm 60 per cent. Heymann's results with combined radium and X ray treatment (the radium very heavily filtered) gave with 66 cases (94 per cent. inoperable) at five years a cure of 28·8 per cent., which compares very well with the average 25 per cent. of operation cure on selected cases. In cases where radium alone is used the usual technique (except in early cases) must often be considered imperfect; dosage is far from being even throughout, and as Bumm pointed out, intracervical radium cannot affect the pelvic glands or prevent recurrences there. Hence his advocacy of X ray treatment for the whole pelvis, with radium given locally, or X rays after operation. Some facts suggest that combined surgical and radiological technique, as in breast cases, may give better results than either alone. Thus Warnekros has reported, out of 190 cases at Bumm's Clinic, 72 per cent. of cases which had prophylactic radiation recurrence-free after five years, compared with 36 per cent. in those who had no X ray treatment. Similarly, Heimann reports 65 per cent. to 10·6 per cent. These results show the great advantage of a well-planned and well-performed X ray course as a supplement to operation. Radium has frequently been given prophylactically a fortnight or so before operation, and in many such cases little or no sign of malignancy has been found remaining in sections of the area involved. Inoperable cases have frequently been rendered operable after radium treatment. This pre-operative method has not yet, however, been carried out on any large series of cases.

In uterine sarcoma Wintz calculates the X ray results are three times better than the operative—the latter giving about 20 per cent. of cures. Of five inoperable and apparently hopeless X rayed cases, four were at four years well and recurrence-free. He has shown the diagnostic value of X ray treatment in differentiating between myoma and sarcoma, the latter reacting in a few weeks, the former taking months to become smaller. Some cases of primary ovarian malignancy have been reported as having done well, or inoperable peritoneal extension or recurrences. I have had good results in a few such cases. Like testicular growths, ovarian neoplasms are often very radio-sensitive, and pelvic masses may sometimes regress quickly, relieving pressure or other symptoms. A number of cures of vulvar carcinoma have been reported, both by radium and by X rays; with the latter the Erlangen method of radiation from a great distance (to give more equal intensity in the depth) has undoubtedly marked a great technical advance.

Abdominal Conditions.

It is interesting to note that stomach cancer was the first cancer to be treated by X rays (Despeignes, 1896), but it is likely to be one of the last to yield to radiation or to any other form of treatment. Compared with gynæcological cancer, that of the stomach occupies a most unfavourable site, surrounded as it is by vitally important glands and other structures. It is impossible to avoid radiation of the pancreas, and the spleen to some extent, but special care should be taken to avoid the suprarenals—for example, by Holfelder's method of oblique radiation. One case already has been reported of a man, previously vigorous, having died with adrenal insufficiency, after spinal radiation for supposed spondylitis of the lower dorsal vertebræ. Both sides were radiated (cross-fire), and both suprarenals damaged.

After partial gastrectomy radiation is advisable, but very few cases have so far been published. Primary cases with not too marked cachexia should, in my opinion, be given the chance of X ray treatment, as extraordinary results are sometimes witnessed; Werner had two such cases whose cures extended over eight years. Natural recovery is not, of course, impossible, but is improbable in two such cases at the same clinic. Cancer of the colon sometimes reacts well, with or without resection or colostomy. Each case must be treated on its merits, and combined surgery and radiation are usually indicated. A few clinical cures are reported with X rays or radium, or the two combined, in rectal carcinoma. Schmieden has here worked out a combined surgical and radiological technique which he says is giving very good results.

Sarcomata.

There is a considerable literature dealing with sarcomata, apart from uterine sarcoma. Perthes and Jüngling have summarised conclusions which may at present be accepted, based as they are on treatment of 47 cases. (1) In all cases of inoperable sarcoma, X rays should be tried, even in large glio-sarcomata of the brain. The remarkable results in hypophyseal tumours are noteworthy. (2) Lympho-sarcomata should be radiated rather than operated on, as they react perfectly well to radiation. (All of 17 Erlangen cases, all of 16 Tübingen cases did well; Werner has clinical cures lasting over five years.) (3) Periosteal sarcomata of pelvis, shoulder, or limb joints give better results with radiation than with operation. (4) Myelogenous sarcoma sometimes regresses without any treatment, and the results of resection are good, but if amputation is considered radiation should first be tried. (5) Maxillary sarcomata, if operable, should be resected; they are difficult to radiate satisfactorily, and all the early recorded cases were under-dosed. (6) Skin sarcomata should first be radiated—if refractory, as some melanotic ones are, they should be excised. Jüngling does not confirm Seitz and Wintz's observation that sarcomata which have been operated on or have recurred react worse than non-operated cases. He confirms what Kienböck noted, that local recurrences are rare after a radiation cure. The two difficulties with sarcomata are, first, that a certain number (20 per cent.) of all surgical sarcomata are refractory to 70 per cent. radiation doses; there is, therefore, no "sarcoma dose." Holfelder advises considerably larger radiation doses in surgical sarcoma than suffice for gynæcological. The second difficulty is general metastasis, but many of the distant sarcomatous metastases are responsive, even when very large. Jüngling points out that cachexia with sarcoma has not the bad significance of cachexia with carcinoma.

Local Results of Radiation.

The results of radiation on a tumour which reacts well may be three: (1) Complete disappearance, by absorption of the degenerated tumour cells; or (2) lessening in size of the tumour, but persistence of a residue, usually firm proliferative connective tissue (it may be advisable in some cases, if possible, to remove this by operation, but if not it should be watched for many years for signs of renewed activity); (3) reduction to a certain degree (as Blumenthal has shown) and then no further change, the tumour appearing biologically dead. Rapid increase in size and generalisation are sometimes observed in cases under-dosed, or refractory, or already too widespread;

and as septic malignant tumours (of the neck, &c.) sometimes slough rapidly after heavy radiation, fractional dosage methods are here advisable if the case seems at all suitable for treatment.

Local results, apart from those in the tumour, are usually temporary, such as those in the skin, salivary and intestinal glands. Burns and fistulæ as results are but the "children's diseases" of radiation therapy, as Döderlein says. Skin and lung induration as a possible result of heavy dosage have to be considered; they usually pass in the course of a few months. The possibility of local œdema should be considered beforehand, especially in laryngeal and mediastinal cases; it has not so far been reported in brain cases. The majority of cases of serious damage already reported have been in the larynx or trachea, and in the bowel (ileum, cæcum, and sigmoid). From some of the large doses published from some quarters it would seem that unjustifiable risks are being taken by a few workers, though the risks in advanced cases do not in any way approach the operative risk. In rectal cases, for example, there is often a large septic element; hence widespread necrosis may be seen after any interference, whether operative or by radiation. However, in the majority of cases of bowel damage reported, technical errors cannot be excluded or were evident, the doses being too frequently repeated, or there was over-dosage, this being probable particularly in some of the cases where combined radium and X ray treatment was given. If there was no technical fault, then there were bowel adhesions or a site of lessened resistance due to previous operation or disease. In all the cases of bowel damage (with one death) reported by Fried operation had been performed previously, showing the great care necessary to avoid over-dosage in post-operative prophylactic abdominal work.

General Results.

Undesirable general results from radiation are usually seen in the blood or intestinal or ductless glands. In a considerable series I have not found as much blood-change as I had been led to expect, nor have I had trouble with bowel sequelæ; in one stomach case there was slight but definite adrenal insufficiency for about two months, in spite of only one adrenal having a considerable dose. I have no doubt that advanced patients treated by radiation alone do not respond locally or generally as well as those to whom some supplemental treatment is also given. Werner was one of the first to show the value of arsenic and other preparations as adjuvant to radiation, and Blumenthal has emphasised the value of combined treatment, radiation plus arsenic or iodine, &c. Colloidal copper and lead, protein, and a multitude of other injections have their advocates. Rubens-Duval has an elaborate scheme for increasing the defence of the patient against cancer, by combined opotherapy, remineralisation, sulphur administration, and vaccine-therapy. The last is certainly useful in dealing with combined malignancy and sepsis. Fraenkel has written much about the probable rôle of the endocrine glands in malignancy, advocating stimulation doses to the thymus, spleen, &c. I have tried some cases this way, especially when there has been a superadded infection of a malignant tissue, with results so far inconclusive. Fraenkel's views are interesting, but so far unsupported by clinical facts, as Halberstädter and others have pointed out, or by definite pathological facts, as Karlefors' inconclusive pituitary and thyroid results show. There is no question, however, as to the value of spleen-stimulation doses in improving the blood-picture. At Erlangen this is now regularly done in anæmic cases.

Temporary general effects of radiation such as Rontgen sickness are reduced in intensity by careful previous preparation of the patient, by smelling—e.g., eau-de-Cologne during the séance, by technical methods such as that I described at the B.M.A. meeting last July, whereby the time for the radiation séance may be shortened in certain cases or areas by using wax or other superficial covering, so as to give in a shorter time an equal depth-dose to that given by radiation from a distance of 70–100 cm., or finally, as Wintz has suggested, by earthing the patient when this can be done safely, as the high induced voltage of the patient's body while the treatment is being given is a potent cause of nausea and disturbance.

Present Conclusions.

From the combined surgical and radiological point of view Schmieden has recently published a most valuable paper on the indications for surgical and X ray treatment of malignant tumours. Perthes' detailed views on sarcomata have already been given. Schmieden and his X ray assistant Holfelder have summarised conclusions which represent what may be called cautious progressive present-day opinion: 1. With few exceptions every operable carcinoma should be operated on, with prophylactic post-operative radiation in addition. 2. In addition to post-operative radiation, a single intensive radiation before operation is coming to be considered important. 3. Practically all inoperable carcinomata and all inoperable recurrences should be radiated. This gives in many cases clinical cure, in others it results in operability, often less bleeding, irritation, and pain, as well as limitation of further metastasis. 4. Facial carcinomata, even when operable, can well be treated exclusively by radiation for cosmetic reasons. 5. Sarcomata, as a rule, should only be radiated, certainly in all cases in which operation would cause considerable bodily mutilation. (Any increase in size of the tumour after an efficient radiation should not be considered proof of failure to respond, it is usually only temporary.) Schmieden here gives five essential technical requirements. 11. In the treatment of malignant tumours, along the whole line, X ray work has become superior to radium treatment.§ 12. The time has not yet come when comparative statistics can show the value of operation or radiation.

Werner in a useful summary says that as yet ray therapy only in a proportion of malignant tumours can be compared with surgery in its results. But in carcinoma of the skin, lip, inner cheek, soft palate, upper larynx, thyroid, vulva, vagina, uterus, tumours of the hypophysis and mediastinum, and sarcomata, which often react promptly, radiation may be preferred. All operable new growths not in this series are better operated on than radiated, if one or other procedure must be chosen.

Lines of Advance in Treatment.

Radiation treatment is in rapid process of evolution and there are at least six possible lines of advance: 1. In the engineering and electrical workshop, improvement of apparatus in power and reliability. 2. In the physical laboratory much remains to be done with measurements of dosage, standardisation, calculation of scattered radiation and absorption in animal tissues (this is specially necessary for radium dosage, as Guilleminot and others have noted); the physical side of biological radiation effects—for example, ionisation and osmotic changes in cells and fluids—requires much research. 3. In the post-mortem room and the pathological laboratory, more statistical and experimental work; apart from immunity and gross animal tumour work, the histological tissue reactions to radiation, as Ewing says, seem to require the combined genius of a Waldeyer, a Weigert, and a Virchow to elucidate them; here new methods like vital staining may be of use; and there is a very wide range for biochemical investigation as to the radiation effects on basal metabolism, &c., as to the rôle of the cell-lipoids and cell-decay products, &c. 4. Clinical technique is a most important branch requiring much further working out—for example, anatomical technique of radiation applications to different sites of the body on such lines as Holfelder's in Schmieden's clinic by sectional scaled sheets and models and graphical representation of radiation fields. For the last year I have used scaled drawings in almost every case, and regard this as essential. Auxiliary technique such as diathermy, ionisation, radiation stimulation (ductless gland) dosage, or general minimal repeated radiation or other means for stimulating the patients' immunity requires much further research. 5. In relation to surgery enough has already been said as to the necessity and value of team-work, and the best results have been shown so far in several important spheres to have been the result of close coöperation between surgeon and radiologist. Much still has to be learned as to the value of pre- or post-operative radiation, or both, and when the raying should be given in relation to the operation, and in what types and sites of lesion one or other or a combined method is best for the patient. 6. Finally, auxiliary medical measures require much further investigation; though about 100 substances have already been tried, still in this sphere, some day, may be discovered what may displace both surgery and radiation in the treatment of malignant disease. At present the general management of the cancer patient is too often neglected; open air, exercise, diet are not unimportant in recovery, and the rôle of hæmatinics, colloid, protein, and animal extract injections or transfusion, and of drugs such as arsenic, iodide, &c., is little understood yet.

---

§ (This leaves out of account the improved results attained with the new (American) radium technique—burying of numerous small tubes, and massive surface radiation from a distance.)

From the clinical as from the pathological standpoint there is no doubt, as Ewing has said, that "radiation therapy has introduced a new era in the study of cancer." He has emphasised the experimental evidence recently accumulated as to the artificial immunity against cancer produced by the absorption in the body of radiated tumour tissue. Whatever the ultimate value of radiation treatment may be, alone or as a combined method, from the point of view of immunity, and from the fact that in its mode of action radiation "calls on nature's forces to accomplish the cure," we must hold with Ewing that "the curative action of Rontgen ray and radium . . . . is the first rational therapy of cancer ever devised."

CHRONIC FÆCAL TYPHOID CARRIER SUCCESSFULLY TREATED WITH DETOXICATED VACCINE.

BY JAMES P. WATT, M.B., C.M. EDIN.,
MEDICAL OFFICER OF HEALTH, COUNTY OF ABERDEEN.

CHRONIC typhoid carriers have hitherto proved so resistant to treatment that the following notes of a case treated with detoxicated vaccine with apparent success seem worthy of record.

The carrier, Mrs. X, passed through an attack of typhoid in 1903 while resident in South Africa, and after coming home was associated with five outbreaks of typhoid at the farm occupied by her husband, with a total of eight cases, six of whom were servants, three male and three female, while the other two cases were neighbours who obtained milk from the farm. The cases occurred in the following years: 1904, 2 cases, domestic servant and neighbour getting milk; 1906, 1 case, farm servant; 1907, 1 case, farm servant; 1910, 3 cases, farm servant, domestic servant, neighbour getting milk; 1917, 1 case, domestic servant. In 1909, Mrs. X's husband had a severe illness, which was diagnosed as influenza. He was confined to bed for three weeks, and after getting up had a relapse which confined him to bed for three weeks more. Insomnia was a marked feature of the illness, and it might possibly have been typhoid.

I found Mrs. X to be a fæcal typhoid carrier in 1910 in connexion with the outbreak in that year. Every precaution was taken to prevent further outbreaks, but in spite of these a case occurred in 1917—a domestic servant, aged 18. Early in 1921, I arranged—with the kind coöperation of Dr. David Thomson, director of the Pickett-Thomson Research Laboratory, St. Paul's Hospital, London, who undertook to supply a detoxicated autogenous vaccine—to try a course of vaccine treatment for this case. Some time was lost at first, as Mrs. X developed an attack of diphtheria. As soon as she had recovered, samples of her stools and urine were examined to determine whether she was still a carrier. Examinations were made on April 5th and 15th, May 6th and 24th, June 30th and July 21st.

Treatment.—The sixth sample of stools, examined on July 21st, proved positive, the others having been negative, and after some further delay treatment was commenced in the beginning of December, the dosage in thousand millions being as follows: 1, 2, 4, 6, 8, 10, 12, thereafter rising by additions of 1000 millions each time to 30,000 millions. The vaccine was given by subcutaneous injections at intervals of five days, and the following is a note of the reactions observed.

For the first three injections there were no local reactions, but after that there was always some local reaction in the nature of an inflammatory area round the site of inoculation. This, however, did not increase in proportion to the increase of dose. Sometimes it was more pronounced, and the next time not so much.

It lasted about two days, and then gradually disappeared. The arms were injected alternately, the upper arm being the site of inoculation. There was no constitutional reaction of any kind until the last few doses, when general symptoms of headache, sleeplessness, and very severe backache appeared, while the local reaction got so severe that the arm had scarcely returned to its normal condition when the ten days were up. The treatment was accordingly discontinued for a time.

A sample of stools was examined in the end of March and found to be positive. Another sample taken on June 9th, just after the treatment was stopped, resulted in the finding of an organism giving all the cultural reactions of *B. typhosus*, but not agglutinating with serum. A second sample taken on the 16th and a third on July 15th both gave the same organism. Treatment by subcutaneous injection was resumed in the beginning of September, the same course being repeated, beginning with 1000 millions. At the same time, at Dr. Thomson's suggestion, a course of vaccine by oral administration was commenced, and along with the vaccine were given pills of ox-bile, 2 gr. in each. The vaccine was standardised to a strength of 100,000 millions per c.cm. The dosage for oral administration began with 5 minims per day, and was gradually increased to 2 drachms. The second course of subcutaneous injections was continued from the beginning of September till the middle of November, the dosage reaching 23,000 millions. Subcutaneous injections were then stopped, but oral administration of vaccine was continued.

A sample of stools was examined on Sept. 7th and proved negative. The non-agglutinating bacillus was not found in it. Since then 17 samples have been examined: 2 in September, 4 each in October, November, and December, and 3 in January of this year, and all have been negative. The examination of samples is being steadily continued, in case the absence of typhoid bacilli in the stools is due to an intermittent period, such apparently as she had from April to July, 1921.

Bacteriological Report.

Dr. J. W. Tocher reported on the examination of the stools. The first report (test of March 21st, 1922) gave the typical typhoid bacillus; the subsequent reports (tests of June 9th and 29th, and July 21st) gave as a positive result an atypical bacillus giving all the cultural reactions of *B. typhosus*, but not agglutinating with serum. These three were returned as positive. Eighteen other tests, all negative, were made between Sept. 6th, 1922, and Jan. 26th, 1923. The bacillus isolated in the three tests immediately following the first test was a Gram-negative rod, feebly motile and giving all the sugar reactions of *B. typhosus*. It was, however, non-agglutinable by any of the stock serums in the laboratory. Emulsions of this culture, injected intravenously into a rabbit, failed to produce agglutinins towards this organism. The growth in broth was inclined to form filaments.

An examination of the organism found in the June and July samples was made in another laboratory to which Dr. Thomson sent a sub-culture, and the report made confirms Dr. Tocher's results. The report is as follows:—

"I do not think it is a typical typhoid bacillus (although I agree it gives all the typhoid sugar reactions, &c.). It is very feebly motile, and has a tendency to become filamentous in broth. We plated it again and it appears pure. Now a guinea-pig has been inoculated with it to obtain immune serum to try against all the typhoid-enteritidis group from the Standards Laboratory, Oxford."

A further report says:—

"An emulsion of that bacillus is not agglutinated by any of the Standards sera typhosus, para. A and B, Gaertner and Aertrycke, and so far is not agglutinated by inoculated animal serum. Inoculation with 2 c.cm. of a 24 hours' old broth culture failed to kill a guinea-pig, so that the organism is evidently non-virulent."

Perhaps the most interesting feature in the case recorded is the bacteriological findings in that typical typhoid bacilli were first isolated, and later the organism became atypical, giving the sugar reactions but failing to agglutinate. Neither *B. typhosus* nor the atypical bacillus has been recovered from the stools after 18 successive examinations.

ENCEPHALITIS LETHARGICA:

AN INTENSIVE OUTBREAK IN A SMALL SCHOOL.

BY L. L. FYFE, M.B., CH.B. GLASG., D.P.H. CAMB.,
ASSISTANT COUNTY MEDICAL OFFICER OF HEALTH, WARWICKSHIRE.

ON Oct. 20th, 1922, the head teacher of the council school at Radway, a remote village situated near Edge Hill in the extreme south of Warwickshire, reported to the county medical officer of health (Dr. A. Hamilton Wood) that some of the children in her school were presenting unusual symptoms, in that they were continually dropping off to sleep whilst in school. On the 23rd, acting on the instructions of the county medical officer of health, who in the meantime had made some preliminary inquiries, I investigated the cases and found that four children in all were affected.

CASE 1.—A girl, aged 13. During the afternoon of Sept. 15th, she fell asleep in school and was only roused with the greatest difficulty. The head teacher stated that she had to walk her up and down the playground before she could be sufficiently roused to go home by herself. She remained away from school over the week-end, returning to school on the 19th. Since that time she had attended school daily, but had been continually drowsy, and complained of frontal headache. She fell asleep every day in school and awoke spontaneously after sleeping about an hour and a half. No squint was noticed, but the head teacher observed that the child's writing was not up to her usual standard, the characters showing a shakiness. On Oct. 17th (more than a month after the onset of her illness) she complained of diplopia and has suffered from this at intervals ever since.

Condition on Examination.—On visiting the school, on Oct. 23rd, I found the child asleep at her desk. There was, however, no difficulty in rousing her. When aroused she was quite intelligent and gave a good account of her illness. She was rather pale, had slight attacks of shivering, and complained of slight vertigo. There was an internal strabismus of the right eye—probably a permanent condition, as she wears glasses to correct an error of refraction. She stated that *since* her illness she had double vision unless she wore her glasses; she was quite certain that she had no diplopia prior to her present illness, whether she wore her glasses or not. There was some paresis of the right leg and she dragged the right foot in walking. Temperature and pulse normal. She had been in Radway until the end of the first week in August, when she went on holiday to Sparkbrook in Birmingham, where she remained until the end of the second week in August. During the last fortnight in August and the first week in September she stayed with friends in Walsall Wood (near Birmingham). She returned to Radway on Sept. 7th, and went to school on the following day.

CASE 2.—A girl, aged 14. On the morning of Oct. 9th this child felt sick and vomited once. Since then she had suffered from severe frontal headache and marked drowsiness, having fallen asleep at intervals during the day. On the 20th she complained of dimness of vision on waking in the morning. This, however, passed off and had not since returned. She had had no diplopia. The teacher stated that she noticed that the child's writing was not so good as usual.

Condition on Examination.—On Oct. 23rd the patient was found asleep at her desk. She was easily roused and answered questions intelligently. She complained of slight sore-throat, but the fauces appeared normal on examination. There was, however, slight adenitis of the submaxillary glands. She had slight shivering attacks during the examination and tended to drop asleep. She stated that she had slight giddiness on attempting to walk immediately after waking, but that this soon passed off. There was no squint or diplopia and no apparent paresis of any limbs. Temperature and pulse normal.

CASE 3.—A girl, aged 11, who had been ill since Oct. 11th, complaining of severe frontal headache and drowsiness. She vomited on the first day of her illness, but not since; had been drowsy since the onset, continually dropping off to sleep in school. The teacher stated that not before the 23rd had she had any difficulty in rousing her. Headache was a marked feature in this case; it was not continuous, but she had had severe paroxysms lasting two or three hours every day. Since the commencement of her illness she had had dimness of vision in her right eye, but no squint or diplopia. The teacher stated that she had great difficulty in rousing her on the morning of my visit, and that when she eventually succeeded in doing so the child was quite delirious. She apparently did not recognise the teacher and started hitting out in all directions. When I saw her the delirium had passed off, but she was still confused mentally. She complained of severe headache and dimness of vision in the right eye. There was no squint or diplopia. Temperature 100° F., pulse 110. When attempting to walk she staggered about as if under the influence of alcohol, there being obvious weakness and incoördination of the lower limbs.

CASE 4.—A girl, aged 9. The first sign of illness was on Oct. 13th, when she dropped off to sleep in school and slept for half an hour. She was roused and sent home in charge of an elder brother. She dropped down and fell asleep on the roadside on the way home. On reaching home she slept all the afternoon. She returned to school on the 16th, and then appeared better on the whole, but rather drowsy. On the morning of the 18th she fell asleep in school again and was sent home. Her parents, however, sent her back to school in the afternoon, when she again fell asleep. On the 20th she slept most of the morning in school, and on being roused at midday fell asleep in the act of drinking a cup of cocoa. When seen by me she was asleep at her desk; she was roused comparatively easily and made no complaint of anything beyond "sleepiness." There was no headache. She had previously lost an eye through an accident, so no diplopia was possible; there was slight conjunctivitis of the remaining eye and a slight "puffiness" round the orbit, but no squint. There were also definite choreiform movements of the head and the left side of the face. On being asked to walk she presented eversion and dragging of the left foot. Temperature 99·4° F., pulse 100.

In view of the above symptoms I formed the opinion that all four cases were suffering from mild but definite attacks of encephalitis lethargica, and gave instructions that they should be excluded from school. On Nov. 2nd, accompanied by Dr. A. C. Parsons, medical officer of the Ministry of Health, I again visited the cases and found them in the following condition:—

CASE 1.—General condition much improved. Had had no further attacks of somnolence, but suffered occasionally from headache. She stated that she still had diplopia when not wearing her glasses. There was still slight paresis of right leg.

CASE 2.—Had had no further attacks of somnolence. The child stated that she had an occasional slight headache, but was otherwise quite well.

CASE 3.—General condition much improved. There had been no further attacks of somnolence; vision had been normal. Still had occasional headaches, but were not so severe and did not last so long. She was quite steady on her legs, there being no signs of the weakness and incoördination noticed on Oct. 23rd.

CASE 4.—Had had no further attacks of somnolence. There was still some paresis of the left leg. Choreiform movements of the face and head still present, but not so marked.

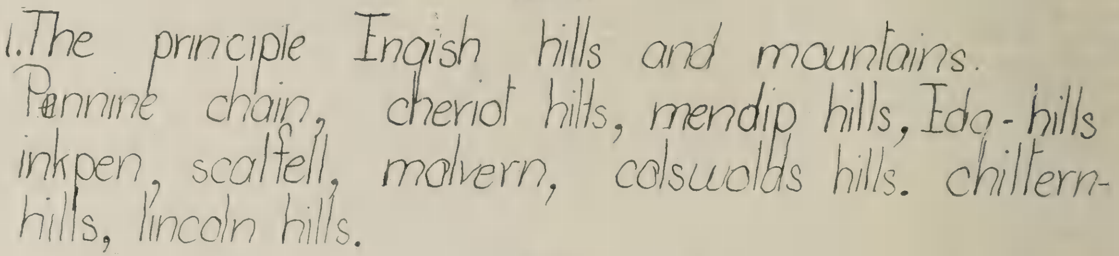
All four cases were again seen by me on Nov. 9th, 1922, and the following notes were made on their condition:—

CASE 1.—Now appears to have completely recovered, but states that she still has diplopia when not wearing her glasses.

CASE 2.—Appears to be in good general health. Has had no drowsiness, but states that she still has occasional headaches.

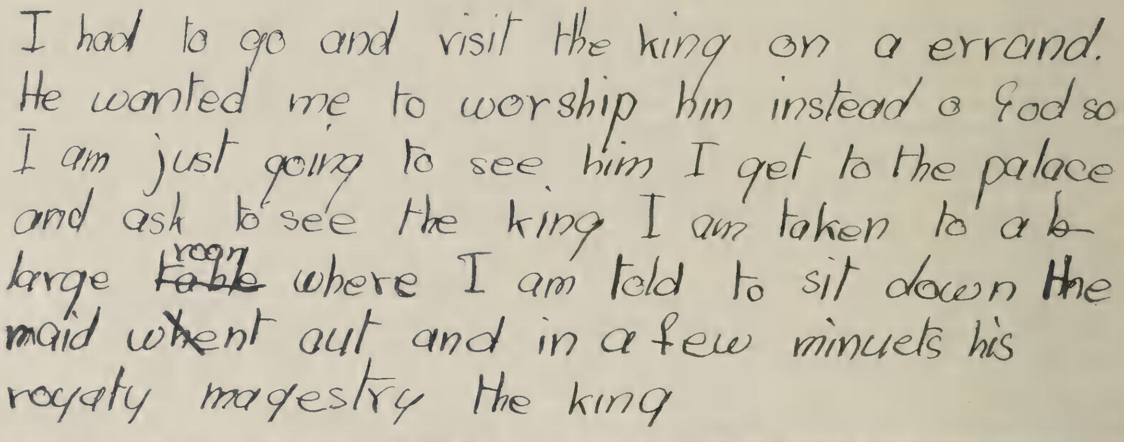
These Specimens of Handwriting Before and After the Attack of Encephalitis are the Work of Case 3, and are typical of all Four Cases.

BEFORE.



1.The principle Engish hills and mountains.
Pennine chain, cheriot hills, mendip hills, Ida-hills
inkpen, scalfell, malvern, colswolds hills. chiltern-
hills, lincoln hills.

AFTER.



I had to go and visit the king on a errand.
He wanted me to worship him instead o God so
I am just going to see him I get to the palace
and ask to see the king I am taken to a ~~b~~
large ~~table~~ room where I am told to sit down the
maid whent out and in a few minuets his
royaty magestry the king

CASE 3.—This girl has now completely recovered and has no symptoms of any kind.

CASE 4.—Choreiform movements of the face and head are much better. Paresis of leg has completely disappeared.

On Dec. 6th all four cases were seen again, and as they appeared to have completely recovered, permission was given for them to return to school. On the 12th the head teacher wrote to me stating that she was not satisfied with the condition of the children and requested that I should see them again. On arrival at the school the head teacher informed me that Cases 1, 2, and 3 had all, on returning to school, shown symptoms of hysteria. (The fourth case had been sent away for a holiday, and was reported to have made a complete recovery.) They were unduly emotional, and all had had fits of crying and laughing; they also complained that their colour-sense was defective. The head teacher had noticed that their school work was far below their usual standard. (A specimen of work is given herewith.) She considered that they were all anxious to do their best, but that they were unable to concentrate their attention for any time, and that they very soon showed signs of mental fatigue.

When seen by me all three children were in excellent physical condition, and on my arrival at the school they were taking an active part in the games in the playground. On examination they all three presented one marked symptom—viz., a very definite defectiveness of memory for recent events. None of them could give an accurate account of the lessons in which they had been engaged in the earlier part of the day. As a control, three normal children, picked at random, were asked the same set of questions and the difference between their answers and those of the three patients was most striking. Their colour-sense and visual acuity appeared to be quite normal.

On Feb. 6th, 1923, all four cases were seen again:—

CASE 1.—The head teacher reported that for the last fortnight she has noticed a trembling of this girl's legs; she stated that the girl still has frequent attacks of hysterical laughing and crying, and that her school work, although showing slight improvement, is still considerably below normal.

On examination a marked tremor of both lower limbs was found—the condition being so marked that when the child sits on a chair there is a continual tapping on the floor with her feet, which she is quite unable to stop unless she puts her weight on to the limbs. The limbs are slightly spastic and there is no loss of power. The child says she can walk quite easily and appears to do so. Both knee-jerks and the tendo Achillis jerks are considerably exaggerated.

CASE 2.—This child was reported to have had tremor of the right leg for the last fortnight. She has also had hysterical outbursts, and her school work is still below her usual standard. On examination there was a gross tremor of the right leg, the right arm, and a fine tremor of the right side of the face, the latter being most marked round the orbit. The child was quite unable to keep her leg or arm steady. Knee, tendo Achillis, and triceps jerks all greatly exaggerated, the slightest tap causing the limb to "fly out." She states that the tremor continues all day, getting worse towards evening, or when she is tired, and that after she has walked for some time she is conscious of loss of power in the leg.

CASE 3.—This case continues to improve. Her school work is hardly back to her usual standard, but the head teacher considers that she is making steady progress.

CASE 4.—This child appears to have made a complete recovery.

Remarks.

This small epidemic of encephalitis lethargica appears to present several features of interest. It seems reasonable to presume that Case 1 caught the infection some time during the first three weeks in August, and the first week in September. She was apparently incubating the disease when she returned to school on Sept. 8th. This suggests an incubation period of at least nine days, as it is highly improbable that she contracted the disease in the remote village of Radway, which is situated four miles from the nearest railway station, the nearest towns of any size being Warwick and Stratford-on-Avon, 15 and 12 miles away respectively. Her three school companions, none of whom had been out of the village for some months previously, with the exception of a single visit to Stratford-on-Avon by Cases 2 and 3, fell ill on Oct. 9th, 11th, and 13th respectively, roughly a month after they were first exposed to infection. One cannot, of course, draw any conclusion respecting the incubation period on this account, as Cases 2, 3, and 4 were presumably daily exposed to infection from Sept. 15th onwards. It is interesting to note that in the school in question there was no overcrowding and that the hygienic conditions are exceptionally good, particularly with regard to lighting and ventilation.

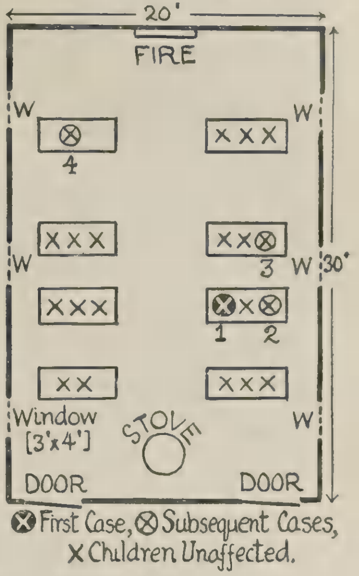
The room in which the cases occurred has adequate cross ventilation from six windows, supplemented by an open fireplace and an iron stove with flue.

The measurements of the room were as follows: Area of room, 20 by 30 ft. (600 sq. ft.); cubic space, 7200 cub. ft.; room occupied by 11 girls and 10 boys, and 1 teacher, total 22 persons; cubic space per child, 327 cub. ft. (more than three times the amount required by the Board of Education).

Another point of interest with regard to this outbreak is that there was apparently a definite infection from the first case to the subsequent ones. According to the Report on Encephalitis Lethargica (1922, No. XI.), published by the Ministry of Health, in only one instance previously—viz., an outbreak in an institution in Derby—has such a definite case-relationship been established. Points of minor interest are the mild and ambulatory type of all four cases, and in spite of the mildness of type, the persistence of symptoms for a comparatively long time. In three of the cases there remains at least three months from the onset a distinct intellectual weakness, and in two apparently a definite lesion of the nervous system.

In conclusion, I would like to express my indebtedness to Miss Turner, the head teacher, for the remarkably accurate histories of the cases with which she supplied me, and to Dr. Hamilton Wood for his permission to publish this article.

Rough Plan of Schoolroom showing Distribution of Affected Children.



Note by DR. A. HAMILTON WOOD.

As is shown in Dr. Fyfe's report of this interesting outbreak, the recorded cases, while being undoubted cases of encephalitis lethargica, were all mild in character, but fortunately not so mild as to escape detection. The symptoms of lethargy and somnolence might in some instances be so indefinite as to make the recognition of the true nature of the disease extremely difficult. Notwithstanding the mild character of the disease in this particular outbreak, sleepiness being the chief early characteristic shown in each case, late sequelæ appeared after the children had apparently recovered. This account should be of considerable interest and significance to school medical officers, owing to the possibility of the discovery of obscure nervous manifestations, mental as well as physical, in children whose histories provide little or no indication of a cause for such disturbances. The report also demonstrates the need for careful and continued observation of all children associated with such an outbreak with a view to discovering possible missed cases, although I am not prepared to say how far this is of importance from a public health point of view, since the duration of infectivity in encephalitis lethargica has not yet been definitely indicated. Dr. Fyfe's investigation of this outbreak was made not only in close collaboration with the Ministry of Health, but much useful information which assisted him materially in the conduct of his inquiry was gained from Dr. A. C. Parsons's "Ministry of Health Report on Encephalitis Lethargica, 1922, No. XI.," which was fortunately published only a few weeks before this epidemic occurred.

WEST RIDING ASSOCIATION OF GRADUATES OF EDINBURGH UNIVERSITY.—The Yorkshire Association of Graduates of the University of Edinburgh met at the Midland Hotel, Bradford, on Jan. 24th. It was decided that the society be known in future as the "West Riding Association." An enjoyable dinner followed at which 60 members and guests were present. The President, Dr. Rabagliati, proposed the toast of the University. Prof. Lorrain Smith, the guest of the evening, in an excellent reply, traced recent developments and changes in the University, referring especially to its connexion with Paris, and to the recent lamented loss of several of its distinguished teachers. He congratulated the society on its successful resuscitation, and took back the best wishes of the graduates to their alma mater.

Clinical and Laboratory Notes.

TWO CASES OF
ACUTE LYMPHATIC LEUKÆMIA.

By W. E. Cooke, M.D. Liverp., F.R.C.P. Edin., D.P.H.,

HONORARY PATHOLOGIST AND BACTERIOLOGIST, ROYAL ALBERT EDWARD INFIRMARY, WIGAN.

The following cases have several points of interest.

Case 1.—A female, aged 3 years, was healthy until three weeks before admission to hospital, when her parents noticed that she was paler than usual. She was admitted on Dec. 30th, 1921, and died the same night with symptoms of cardiac failure.

Post-mortem.—Cadaver pale ; purpuric spots on legs and chest ; no superficial glandular enlargement ; purpuric spots on pericardium and pleuræ. Heart pale and flabby ; thymus normal. No enlargement of mediastinal glands ; mesenteric glands markedly enlarged ; spleen slightly enlarged ; liver and kidneys large and pale. Bone marrow of femur pink in colour.

Blood Film.—A film was taken on admission and showed lymphocytes 89 per cent., myelocytes 5 per cent., polymorphonuclears 3 per cent., transitionals 1 per cent., large mononuclears 2 per cent. The small lymphocytes predominated, being 76 per cent. to 24 per cent. of the large variety. Anisocytosis was marked and normoblasts and megaloblasts were frequent.

Histology.—Sections showed the usual lymphatic infiltration in all the organs, the bone marrow of the femur appeared devoid of fat and consisted chiefly of lymphocytes and red corpuscles.

Case 2.—Male, aged 2½ years. A month before admission the cervical lymph glands were noticed to be enlarged. Admitted with acute angina on August 1st, 1922, and died the same night.

Post-mortem.—All lymphatic tissues enlarged ; superficial glands of neck, axillæ, and groins, tonsils, thymus, mediastinal and mesenteric glands very much enlarged ; Peyer's patches prominent. Liver and kidneys enlarged and pale ; spleen very little enlarged ; purpuric spots on pericardium.

Blood Film.—Shows lymphocytes 99 per cent., of which the small variety constituted 82 per cent. and the large variety 18 per cent.

Sections.—All the organs show lymphocytic infiltration.

The points of interest in these two cases are first, the ages, 3 and 2½ years ; second, one is a female; and third, in one case the lymphatic tissue enlargement was confined entirely to the abdominal glands, while in the other all the lymph glands in the body were involved.

THE USE OF RHUBARB IN ACUTE BACILLARY DYSENTERY.

By H. C. Brown, C.I.E., M.B., B.Ch. Camb.,

MAJOR, I.M.S. (RETD.)

(*From the Wellcome Bureau of Scientific Research.*)

Burkitt, writing from Nairobi,[1] in referring to the treatment of bacillary dysentery with rhubarb, says that he knows of no remedy in medicine which has such a magical effect. The following investigation was undertaken with a view to ascertain the way in which the rhubarb acted in this disease, and which constituent was responsible for this action.

In the first place, a solution containing all the purgative constituents of rhubarb soluble in water was used, 1 g. of rhubarb extract (B.P.) was contained in 3 c.cm. of this solution. For a full account of the constituents of rhubarb the paper by Tutin and Clewer[2] should be consulted. Five c.cm. quantities of the above solution were taken and each was planted with 0·2 c.cm. of a filtered 24 hours' broth culture of the following organisms: *B. dysenteriæ* Shiga, *B. dysenteriæ* Flexner, and the bacillus No. 1 of Morgan, the solution was allowed to act upon the organisms at room temperature for varying time limits up to two hours, and then a 3 mm. platinum loopful was taken and planted into 10 c.cm. of nutrient broth. In each case, after 48 hours' incubation, there was growth in the broth tubes, proved by serological or cultural tests to be the growth of the organism used.

In the second instance, another sample of rhubarb extract of the same strength was employed, but in this case the extract had been neutralised to litmus and then 1 c.cm. of N/10 NaOH added to 100 c.cm. to make it slightly alkaline. The test was repeated as in the former case with the same result—i.e., this extract had apparently no action upon the dysentery bacilli in two hours. A third extract also was used in which 6·7 g. of the portion of rhubarb extract insoluble in water was dissolved in a total of 67 c.cm. of water with the aid of 6·6 c.cm. of normal soda solution, the result in this case was the same as when using the extracts made from the soluble portions of rhubarb.

It was then suggested by Dr. Andrew Balfour that the therapeutic action which is claimed for rhubarb, in cases of bacillary dysentery, might be due to its cholagogue action, and in order to investigate whether this was so, a 10 per cent. solution of taurocholate of soda was allowed to act upon a filtered broth culture of *B. dysenteriæ* Shiga and Flexner, as in the above experiments, and subsequently in its place undiluted ox bile was used, but in both cases cultures taken after two hours' interaction at room temperature showed growth of both varieties of dysentery bacilli. The sterile ox bile was obtained fresh from the slaughter-house and was unheated. Knorr[3] has shown that, although prolonged action of ox bile on the Shiga-Kruse bacillus has a damaging effect, yet, under certain conditions, an actual increase of this organism takes place when acted upon by ox bile, and that in the case of the Y strain a definite enrichment occurs; the time limits of interaction used by this observer vary up to 72 hours.

From the above it does not seem to be proved that the therapeutic effect of rhubarb in bacillary dysentery is due to its cholagogue action. The next point investigated was the possibility of the serum of an animal which had been dosed with rhubarb being germicidal to dysentery bacilli. A rabbit was given hypodermically three doses on successive days of 2 c.cm. of equal quantities of the soluble and insoluble extracts of rhubarb, and the serum from this rabbit, and also from a normal rabbit, was allowed to interact at room temperature, at varying time limits up to one hour, with a filtered broth culture of dysentery bacilli. The proportions of sera and culture were the same as used in the above experiments; subcultures showed no difference in growth between the tubes containing serum of the normal and treated rabbit —the growth in each case was tested serologically.

For purposes of contrast and control cultures of *B. dysenteriæ* Shiga and *B. dysenteriæ* Flexner were submitted to the action of the intestinal disinfectant dimol. Five c.cm. of the dimol lavage solution was taken and to it was added 0·2 c.cm. of a filtered broth culture of the above organisms; cultures were taken at varying time limits from 2½ minutes, and all these cultures remained sterile. This lavage solution, therefore, of which one quart is administered, is capable of killing dysentery bacilli in 2½ minutes.

From the above it appears that neither extracts of rhubarb nor fresh undiluted ox bile have any distinct germicidal action upon dysentery bacilli under the conditions of the tests employed, nor does the serum of an animal which has been treated with rhubarb seem to act in this way. The nature of whatever therapeutic action rhubarb may have in this disease, therefore, still remains obscure.

I am indebted to Dr. T. A. Henry, Director of the Wellcome Chemical Research Laboratories, for kindly supplying me with the various extracts of rhubarb.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

A MEETING of this Society was held on Feb. 12th, LORD DAWSON, President, in the chair.

Dr. E. FARQUHAR BUZZARD opened a discussion on

Psycho-Therapeutics.

His paper was published in THE LANCET last week.

Dr. WILLIAM BROWN, after a tribute to the scholarly nature of the opening address, took up what he regarded as one or two debatable points. Dr. Buzzard had stated that in general medicine diagnosis should precede treatment; that might be agreed with in principle, but in practice the present condition of knowledge was such that a diagnosis could often not be arrived at until treatment had been well started. Sometimes general treatment—i.e., analysis—was necessary for diagnosis as well as for treatment; sometimes even a cure was reached before one could be sure of the diagnosis. Another point was the relation of psycho-therapy and its underlying theories to neurology. Dr. Brown agreed from the point of view of general conception, that there should be a close relation between theory and practice in psycho-therapy and theory and practice in neurology, but seeing that in the mental disturbances met with in border-line cases and in mild psychotic cases the mental phenomena were admittedly correlated with changes in a very complex part of the nervous system, the cerebral cortex, the correlation could only be used if there were knowledge of the functioning of the cerebral cortex; but that the physiology of the cerebral cortex was not well enough known to afford an explanation of these processes was a fact with which physiologists like Sir Charles Sherrington agreed. Therefore, although the doctrine of psycho-physical parallelism might be held, yet for a long time to come it would be necessary to deal with psychology independently of physiology. Moreover, the gap between the physiological and the psychological was unbridgeable. With regard to methods of treatment, the study of war neuroses had resulted in a great advance in psychological knowledge; this had definitely proved that Freud was right in attaching great importance to mental conflict and repression in the causation of functional symptoms; but that Freud was wrong in holding that, when tracked far enough, the fundamental cause was of a sexual nature. The war showed that fear alone was a sufficient cause of the psycho-neurotic symptoms met with. War findings had also laid emphasis on the dissociative nature of hypnosis. Forty per cent. of the cases from the firing line were those of functional amnesia with hysterical symptoms, and they were all hypnotised with great ease.

Dr. S. A. K. WILSON confessed that his views on psycho-therapy had changed to some extent since the days when he was a house physician and the old methods of treating hysteria were in vogue; yet there were types of patient with whom these were still successful, who, so long as they got better, were not curious or critical of the methods employed. In mono-symptomatic cases especially, the alleviation or removal of the symptom, or chief symptom, often started the necessary train of processes whereby the patient cured himself. But there was need for a more scientific method, and carrying out the old treatment in the wrong type of case might end in tragedy. Still, the pendulum seemed now to have swung too far in the opposite direction, for almost every type of case was being tackled by psycho-therapy, and on this subject there were many by-lanes being explored and exploited by untrained persons, paths along which the medical profession should lead. Some of the cases he saw which had been dealt with by even recognised psycho-analysts, however, made him somewhat critical. He reminded psychologists that while there was a plethora of literature on psychological subjects, there had been equal activity in the discovery of the earliest forms and signs of organic change in the nervous sytem. It was when every physical channel had been investigated that the psychologist should be asked to step in.

Dr. M. B. WRIGHT emphasised the point that unanimity was not to be expected in life; there were so many types, and there were numerous sets of people who had their own special views as to how life should be looked at. The enormous amount of work which had been done in connexion with the new psychology should not be ignored or belittled. Psycho-analysis was, first of all, an investigation into the mental life of the individual. Much of the criticism against it was unfair because it was made by people who had not conscientiously applied the method to a single concrete case. It required much time, and was often very difficult, as it dealt in many cases with the whole life of the patient. The great future of the method lay in its application to the young, in the nursery and the school.

Dr. DAVID FORSYTH said the disadvantage of most of the methods of psycho-therapy which had been employed was that they were not based on any scientific foundation. Symptoms of a striking character could sometimes be relieved by mere suggestion, but the reason why the patient had developed them remained obscure. It was because of the latter difficulty that he had become attracted to psycho-analysis. As devised by Freud this was an attempt to put the whole of the mental processes on a scientific basis. In ordinary clinical medicine it was not supposed that anything occurred unless there had been a precedent cause, and that should apply to psychical manifestations also; it would lead to an investigation further and further back until a cause was found. The investigation of sex complexes was regarded by some as repugnant, yet they would admit that in the physical domain no organ or function should be an exception in the matter of inquiry and investigation.

Sir STCLAIR THOMSON related a case in which a girl of 20 visited a psycho-analyst of repute, who supplied a written report on the case from his standpoint. Sir StClair Thomson, having received the permission of the writer, read it to the meeting, preferring to make no personal comment on it.

Dr. CRICHTON MILLER said it was necessary fully to grasp the idea that there was more than one cause at work in producing the symptoms being dealt with. He thought one of the reasons of so much criticism of psycho-therapeutic work nowadays was that many psycho-therapeutists, having been produced in war-time, and having had a somewhat crude experience of disease in general, were obsessed by only one possible ætiology; hence they were continually missing points they would not have missed if they had had a longer clinical experience. He agreed that the real place for analytical psychology was not in the consulting room nor in the clinic, but in schools and nurseries. The medical profession was too apt to look upon psycho-therapeutics as a kind of last resort. He deprecated a too narrow specialism.

Dr. T. A. ROSS said many people considered psycho-analysis was a form of treatment, whereas it was a particular form of investigation. When a patient's complexes had been brought from the unconscious into consciousness he was supposed to be better because of that fact. The speaker, however, doubted that. Some practitioners declared they did not practise suggestion on their patients, but they could not help doing so. The mere patient listening without obvious manifestations of being shocked brought great comfort to the patient's mind and did much to start the curative process. With regard to the statement that Freud was wrong in the importance he attributed to sex complexes, where sex was not unearthed it was usually because the investigation stopped short of that point. Sex, being a matter of such strong repression in our present state of society, was bound to loom largely in the psychic complex.

Dr. P. F. **Barton** approached the subject as one who was for 20 years a general practitioner, and dealt with the psycho-analytic method and its success in certain cases, e.g., of torticollis. He had a word to say against ridiculing or treating lightly patients' religious beliefs.

Dr. G. **Crimp** related an instructive case in a young female artist, whose sex complex yielded to a patient and persistent investigation by psycho-analytic methods.

The **President** paid a high tribute to Freud as a great and independent thinker, though he could not be held responsible for all the developments of his disciples. The mind always had played, and must play, a large part in clinical medicine; and he thought it must take an increasing part as civilisation progressed in producing clinical pictures of disease; these pictures would be more and more coloured by the environment of the world. He agreed it was a matter of regret that so few psychologists had had a wide clinical experience in a large hospital before they practised this specialty. Psycho-analysis carried with it certain disadvantages; its length, the tendency to introspection, the bringing into greater prominence of the ego. And the stressing of sex could be extraordinarily dangerous; sex instincts should be kept in abeyance by other faculties. The example which Sir StClair Thomson read out was horrifying, and it was a humiliation to realise that any medical man could write such nonsense. A splendid field lay open to the specialist in this line of investigation in difficult cases.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A meeting of this Society was held on Feb. 1st, with Dr. **Alexander Ogston**, the President, in the chair, when an address on the

Art of Limb-Fitting: A Plea for the Standardisation of Amputations

was given by Dr. **Middleton Connon**. From the experience of five years at the Orthopædic Annexe and Limbless Centre, Ministry of Pensions, Aberdeen, with the supervision of some 1400 cases, Dr. Connon drew some valuable practical arguments in advocating reforms in the performance of amputations in civil surgery. He pointed out that, in spite of the fact that the surgeon in civil cases had the selection of the site of amputation, in too many cases there was a tendency to conform unnecessarily to the "classical" amputations: and that in such cases coöperation between the surgeon and the limb-fitter was essential in dealing with the problems presented. As a result of war experience it had been found that only certain amputations could be fitted with satisfaction to all concerned; other "classical" amputations, which had proved impracticable as a limb-fitting proposition, should, Dr. Connon maintained, be deleted from the text-books, and relegated to lectures on the history of surgery. He reviewed the sites of amputations of the extremities most likely to be satisfactorily fitted, the reasons for their selection, and the stumps which had proved unsatisfactory. He also referred to the great importance of education in the use of an artificial limb, holding that the best method was to start the patient, as soon as the stump was ready, with the artificial limb which he was permanently to have, the limb not being finished off until all adjustments necessitated by the shrinkage of the stump had been made. He deprecated the use of temporary legs, plaster pylons, and so forth. At the conclusion of the paper, various models of artificial limbs were shown by representatives of limb-making firms who were present, and Dr. Connon showed a number of his patients who had been fitted with limbs, and demonstrated their ability to use them to full advantage.

A short discussion followed, in which Prof. J. **Marnoch**, Mr. **Alexander Don**, and the **President** took part. Dr. Connon's suggestions as to the teaching of "classical" amputations were generally supported.

MANCHESTER MEDICAL SOCIETY.

A meeting of this Society was held on Feb. 7th, Sir **William Milligan** being in the chair.

Colonel L. W. **Harrison** read a paper on

Public Medsures for the Treatment of Venereal Diseases.

He said that, as a result of the Royal Commission's recommendations, public authorities were asked by the Local Government Board, and later the Ministry of Health, to frame schemes for the treatment of venereal disease. The principle underlying the recommendations was to stop the spread of venereal disease by rendering the greatest possible number of the infected population non-infective. Conceivably a local authority, when required to frame a scheme for rendering the greatest possible number of the infected of its population non-infective would think out: 1. What were the kinds of people likely to be infected. 2. How to persuade these infected people to consent to treatment. 3. How to keep them under treatment until they had become permanently non-infective. 4. The provision of treatment centres. The people likely to require attention were: 1. Those suffering from active diseases as a consequence of fairly recent sexual misconduct. 2. Those who had been infected in the past but believed themselves cured and were discovered only by reason of having communicated the disease to others, such as wives or children. 3. Those who had acquired gonorrhœa or syphilis innocently, such as wives of infected husbands and their children.

Treatment for Those Innocently Infected.

The innocently affected might require special provision for treatment owing to their probable objection to attendance at a venereal clinic, and Colonel Harrison strongly advised that this provision should be made at existing maternity and child welfare centres. The treatment of infected mothers had given most valuable results in the prevention of congenital syphilis, and no V.D. scheme could be considered complete without the fullest provision for treatment of infected parents. It was not fair that a child should start life handicapped by inherited syphilis, and local authorities should ask themselves anxiously if they were carrying out completely the comparatively simple task of preventing it. Those who were discovered by reason of having infected others should be secured by a system under which wives were persuaded by social workers to send their infected husbands for treatment. Such a system was in operation at St. Thomas's Hospital, and many whole families had been brought under treatment by it.

Treatment for the Ordinary Case.

As to the arrangements for the main body of the infected, Colonel Harrison pointed out the disadvantage of treating large numbers of venereal cases in premises ill-adapted for the purpose, such as out-patient rooms of hospitals. It was economically unsound, as it wasted man-power very seriously and it led to defaulting on the part of the patients, since medical officers did not get a proper chance of treating their cases efficiently, especially in gonorrhœa, and the patients sooner became tired of attending. Experience had shown that premises specially designed for the purpose were necessary if the scheme was to be a success. In many cases voluntary hospitals had not made good provision for venereal treatment, and it would have been better in many cases to have established centres in separate premises. The theoretical objection to "ad hoc" clinics had not been substantiated by experience; they had proved to be just as successful as, if not more so than, the average clinic established in a voluntary hospital, and in future if a voluntary hospital was not willing to give the facilities required for completely efficient work, he would have no hesitation, in towns of any size at any rate, in recommending the provision of "ad hoc" centres.

With regard to the number of centres for a given size population, he thought that these should be few rather than many, since transport was easy and a large centre was more economical than a small one. Clinics of any size should be open all day, say, from 8 A.M. to 10 P.M., in order that patients might attend for intermediate treatment at hours convenient to themselves. Intermediate treatment was a daily business and likely to prove irksome in some cases; it was less so, naturally, if the patient could easily fit it in with his private engagements. It was a great advantage also if new cases could be seen at any hour, but the provision for this naturally depended on the size of the centre.

[A number of slides of the V.D. treatment centre at St. Thomas's Hospital and of the type plans of centres issued by the Ministry of Health were shown here to illustrate the lecturer's ideas on the internal arrangements of treatment centres.]

The St. Thomas's Hospital centre had existed, he said, for nearly three years and was judged to be a success. The initial cost was high, but the running expenses were considerably lower than the average—in fact, the lecturer showed that the whole treatment required for the London area could be carried out in five centres at a cost which was £16,000 less than was at present being spent, though the London centres were not more expensive than those in the large provincial towns.

With regard to the staffing arrangements, Colonel Harrison held strongly that each treatment centre should be under the control of one director, and he expressed his view of the great advantages which accrued to the public when the director of a centre was thoroughly imbued with the public health spirit. He pointed out that his work is to protect the community from venereal disease and that the treatment which he directs is to be regarded in the light of a means to that end. For the same reason he considered as most important that the closest sympathy should exist between the public health department and the directors of V.D. treatment centres. At present those in charge of treatment centres were too closely shut up in water-tight compartments, and regarded their patients rather from the individual than from the public health point of view. This was a public health scheme, designed to render non-infective the greatest possible number of infected persons, and he considered that that end would be served only by the determination of all concerned to allow no other consideration than its attainment to prevail in their councils on the subject.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held recently, Dr. D. W. LIVINGSTONE, Vice-President, being in the chair.

Dr. D. H. RICHARDS and Mr. GEOFFREY BATE read notes of two cases of

Androgynoid Pseudo-hermaphroditism.

Dr. Richards said that the two cases were sisters, aged 21 and 18, and that his attention had been drawn to the cases by his having been called to the first as an emergency—the girl (?) having a painful and irreducible swelling in the groin. Inquiry and examination showed that although she was to all outward appearances a girl, she had never menstruated. Suspecting the nature of the case he sent the patient to Mr. Bate at the County Hospital. The nature of the first case having been decided, he made inquiry as to the rest of the family and found that the younger girl had swellings in both groins and had a similar history as to menstruation. A younger sister, aged 14, is now suspected of being in a similar condition but has not yet been examined.

Mr. Bate said that before operating on the first case he had carefully examined the patient. Externally the whole configuration of the body was feminine; the breasts were very fully developed although pubic hair was almost absent; the labia, clitoris, and hymen were normal but somewhat small. Careful examination of the vagina through a Kelly's speculum failed to reveal any cervix or sign of any cervical canal. The vagina ended about 1½ inches from the hymen in a rounded roof. Bimanual examination, though difficult owing to the small size of the orifice, failed to reveal any evidence of uterus, ovaries, or tubes, though there was a very slight median thickening of the vaginal vault in the middle line. The inguinal swelling, when removed, proved to consist of a rounded body with a thick fibrous coat, to which was attached a small cyst. This body, when examined, was found to be a testis, and was attached below by a firm gubernaculum to the pubes, and was continued upwards in a cord which passed out of reach towards the kidney. The second case was in every way similar, though swellings were present and removed from both groins. The elder girl was distinctly feminine in her ways and was pretty. The second girl, though apparently feminine, was less of the "pretty" type than her sister, and she presented the bilateral swellings which proved to be even more definitely developed testes than in her "sister's" case. Mr. Bate illustrated his notes by lantern slides showing the feminine characteristics of the patients and the histology of the testes removed.

Dr. H. M. GALT said that although the lantern slides were not quite satisfactory owing to the staining not being suitable for lantern work, the slides themselves were on view and the appearances were quite clear. There could be no doubt whatever about the structures present. Although the development was to a certain extent of the infantile or immature type the typical testicular structures were all present. There was a well-marked tunica albuginea, and in the more central portions of the sections the tubuli seminiferi were present in abundance and were quite characteristic, showing the convoluted structure of the tubes and the lining of the special columnar cells. He said that from the appearances there was little doubt that the organs were functionally inactive, and that there was only a rudimentary fibrous mass representing the epididymis. There was also shown in one section what appeared to be a rudimentary vas deferens; this was in the form of a thick-walled muscular tube but without any definite mucous membrane.

Mr. BATE showed two cases of

Pseudo-coxalgia,

one bilateral, and a case of traumatic epiphysitis of the hip for comparison. He then read a paper on the former condition, showing a series of some 30 lantern slides illustrative of the condition, including radiograms of the cases shown and of other morbid conditions of the hip for comparison. He discussed the ætiology and treatment of the condition and emphasised the absolute necessity of radiographic evidence in the diagnosis.

MIDLAND MEDICAL SOCIETY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this Society was held in the Medical Institute, Birmingham, on Jan. 31st. Dr. C. E. PURSLOW, the President, took the chair.

An Intracranial Lesion for Diagnosis.

Dr. J. D. STANLEY showed a patient with an intracranial lesion for diagnosis. The case was that of a middle-aged man, who had definite paralysis of the third, fourth, fifth, sixth, and seventh cranial nerves on the left side, with no signs of spasticity of the lower limbs. The cranial nerves on the right side were normal. Dr. Stanley believed that the man had a "surface" lesion on the left side of the mid-brain, but pointed out that it was difficult to conceive a lesion of this type which would spare the right third nerve. The W.R. was negative and radiograms did not help.—Mr. Beatson Hird, speaking of the appearance of the left eye, which was immobile, anæsthetic, and secondarily infected, said he had seen similar conditions resulting from tumours near the basi-sphenoid.—Dr. Stanley Barnes agreed with Dr. Stanley that this lesion was a surface one. In his opinion the lesion extended backwards from the foramen lacerum anterius, and was probably either a tumour of the dura mater or a slow suppurative process beneath it.

Œdema of Leg Associated with Albuminuria.

Dr. J. W. Russell showed a young woman who had œdema of the left foot and leg associated with albuminuria. The œdema was always worse in summer. He stated that some time ago he had seen another exactly similar case. Physical examination revealed nothing abnormal, but on screening the chest, Dr. H. Black had drawn attention to a very definite scoliosis. Investigation of the albuminuria following various postures had led to the interesting conclusion that it was derived principally, if not entirely, from one kidney. Dr. Russell had been completely unable to find any plausible explanation for this curious association of unilateral œdema with albuminuria, until Prof. J. C. Brash had suggested that it might depend on the presence of a subcardial vein on one side, a rather unusual anatomical abnormality.

Mr. A. W. Nuthall suggested that the ureters should be catheterised, but Dr. Russell thought this unjustifiable in the case of a perfectly healthy young woman.

Excision of Upper End of Femur.

Mr. G. P. Mills showed a patient after excision of the upper end of the femur (the operation had been undertaken for dislocation of the hip-joint after septic arthritis). The surgical result was disappointing inasmuch as the shaft of the bone had not remained in the acetabulum. The functional result, however, was excellent as the patient got about comfortably, and could walk a considerable distance, whereas prior to the operation she had been crippled and had suffered much pain.

Mr. Mills also showed two children after successful tendon transplantation.

Mr. Naughton Dunn congratulated Mr. Mills on his results. He stated that tendon transplantation was usually successful, providing that the fundamental principle underlying it was not neglected—namely, that a muscle used for replacing another should be one with which the latter was usually associated in function.

Suprarenal Tumour with Metastases in Skull.

Mr. R. G. Abrahams showed specimens from a case of suprarenal tumour with metastases in the skull. The primary tumour had been palpable before any metastasis had appeared. This, Mr. Abrahams stated, was very unusual, but in the course of a brief discussion, Dr. Stanley and Dr. A. P. Thomson stated that they had had similar cases.—Mr. Nuthall discussed the question of surgical interference in those cases in which the abdominal tumour was palpable, and there was no obvious metastasis.

Hunterian Society: Annual Dinner.—The annual dinner of this society was held at the Café Royal on Feb. 13th, Dr. Fortescue Fox, the President, in the chair. After the loyal toasts the Memory of John Hunter was celebrated in silence. Mr. James Berry then proposed the health of the Hunterian Society, to which the President replied with a statement of the position in which the society now stands, a position which has so rapidly improved that future success might, he thought, be taken for granted. The toast of the Royal Colleges and Kindred Societies was briefly proposed by Sir Arbuthnot Lane, the responses coming from Sir Humphry Rolleston, Sir Anthony Bowlby, and Dr. Campbell McClure. The toast of the Guests, proposed by Dr. Langdon Brown, was replied to in amusing terms by Sir Francis Newbolt, K.C., and the Very Rev. Dean Inge. There was a large attendance, the number of ladies being unusual, and the speeches were interspersed with songs.

Reviews and Notices of Books.

APPLIED PHARMACOLOGY.

By A. J. Clark, M.D., F.R.C.P., Professor of Pharmacology in the University of London. London: J. and A. Churchill. 1923. Pp. 390. 15*s*.

This book differs much from other pharmacologies. It does not show what one may call the bare bones of pharmacological facts to any great extent: it is physiological function which is brought to the front. At times we find before us, as we read, a rational therapeutic volume, at others we might be reading an extraordinarily interesting manual of physiology, which is thoroughly up-to-date and puts to shame, in its lucidity, many recent works professedly on that subject. The main characteristic of the book is that, while the subjects selected are therapeutic, the analysis of these subjects is pharmacological, and the pharmacology is based, as it should be, on physiology. No drugs are discussed which are of scientific interest only, in so far that they cannot be applied to human beings, and, on the other hand, no note is made of the numerous drugs in therapeutic use of which the pharmacology is entirely unknown. These two limitations allow the book to be compressed into reasonably modest space.

The first few chapters centre round disinfectants and drugs which destroy parasites of all types. Then, with alcohol, we pass on to the nervous system, and from that to the other systems of the body. The last part of the book is devoted to subjects which have only recently made their way into pharmacology: vitamins, radiations, endocrine glands, immunity, the action of products of protein breakdown, and the physiological standardisation of drugs. It will be seen that the subject is treated in logical sequence, unhampered by time-worn ideas and formulæ. The book will be very useful to all practitioners who, with a practical knowledge of remedies, wish to bring themselves up-to-date in the application of modern physiology and pharmacology to the drugs they have in everyday use.

The charm of the book lies largely in the fact that it gives in readable and not too technical language just what the thinking practitioner wants to know about his drugs. For the medical student this book may not suffice, since his syllabus is not completely covered; but with whatever manual he chooses to fill the gaps, he will be well advised to study Prof. Clark's book before he goes forth to practise.

DISEASES OF THE GUMS AND ORAL MUCOUS MEMBRANE.

By Sir Kenneth Goadby, K.B.E., M.R.C.S., D.P.H. Cantab. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. With 106 illustrations in the text and 8 coloured plates. Pp. 366. £2 2*s*.

In this volume Sir Kenneth Goadby has given an account not only of the diseases and disorders of the gums and mucous membrane of the mouth, but has described mouth symptoms and signs in certain general diseases. He has also sketched with vigour the effect of unsatisfactory mouth conditions upon general health. He has omitted description of disorders of the teeth. There has been of recent years an unfortunate tendency to confuse gingivitis with pyorrhœa; the author's teaching on the subject is clear, he is at pains to describe in detail what pyorrhœa is, how it may affect general and local health, and how it should be treated, but he is very careful to describe the differential diagnosis between pyorrhœa and other conditions bearing a superficial resemblance to it.

On the question of wholesale dental extractions his teaching is very sound; it amounts to this: first prove the case against the tooth or teeth, then, if sentence of execution must be passed, let the clearance of the mouth be carried out in small stages; he points out the danger of opening up flood-gates of sepsis by wholesale extractions at one sitting. The practice of removal of teeth as a diagnostic measure is strongly condemned; with the use of the simple diagnostic methods described in this book it should be possible to recognise the condition of the tooth-socket without recourse to preliminary extraction. X ray diagnosis is well described; the danger of regarding localised areas of rarefaction as evidence of incurable bone destruction is emphasised and the possibility of temporary calcium deficiency of the alveolus is pointed out. The simulation of X ray appearances of periodontal disease by the senile thickening of the cementum is demonstrated by useful plates. The author writes with authority upon the oral manifestations of metallic poisoning; he regards the "blue line" as evidence of lead absorption, but not necessarily of lead poisoning, and notes how rapidly it may disappear on protection of the worker from lead or the removal of tartar.

A considerable section of the book deals with the bacteriology of the mouth: the organisms of Vincent's angina and its allied conditions are fully described. There is a useful chapter upon the causes, manifestations, and treatment of facial neuralgia. The author is impressed by the work of E. Mellanby on the effect of vitamin deficiency in the food of the child or the nursing mother upon the jaw and gums of the infant, and he points out that rickets may have effects upon these which, though they may easily pass unrecognised at the time, may be associated with more obvious trouble later in life.

The value of the book is increased by many microphotographs and plates of a high order and by an unusually complete index.

DISEASES OF INFANCY AND CHILDHOOD.

Their Dietetic, Hygienic, and Medical Treatment. Ninth revised edition. By LOUIS FISCHER, M.D., Attending Physician to the Willard Parker and Riverside Hospitals of New York City; Physician in Charge of the Infantorium, &c. Philadelphia: F. A. Davis Company. 1922. In two volumes. Pp. 1152. $12.00.

THIS work has already run through eight editions. It deals not only with general diseases, but also with the acute infections and much matter that is usually left to treatises on special subjects. The two volumes contain nearly four hundred illustrations, of which many are reproduced in colour. In spite of the size of the work many important diseases are dismissed with unusual brevity, whilst other articles contain statements scarcely in accord with orthodox teaching. Thus, an underlined paragraph on p. 322, which states that "Intussusception usually causes a distension of the abdomen from the side of the cæcum," conveys —if we have understood the author's meaning—an idea quite contrary to the belief of most experienced observers. This is but one example of the evidence of hasty writing which has impressed us whilst reading these volumes; we hope that the future may see them corrected, as they detract from the book's value. The descriptions of many modern reactions, such as the Schick reaction, and the responses to foreign protein inoculation are very thorough.

CHEMISTRY.

Smith's Intermediate Chemistry. Revised and re-written by JAMES KENDALL, Professor of Chemistry, Columbia University, New York; and EDWIN E. SLOSSON, Editor of *Science Service.* New York: The Century Co. 1922. Pp. 566. 8*s.* 6*d.*

IN modest compass, the revised and re-written edition of this book forms a useful foundation to the subject of chemistry. It contains the minimum that every student, whether of science or medicine or other technical profession, should know. A student having read it will desire to extend his information, and there are not many authors who can impart facts, explain their meaning, and at the same time produce a wish for more. In the introduction, under the title "Why Study Chemistry?," Mr. Slosson gives many sound justifications for this study, among them that "Chemistry is especially fitted to give training in scientific thought, for it is experimental from the start and if properly learned inculcates self-reliance and independence of thought. In its manifold bearings it has an interest and usefulness for everyone, as it gives an understanding of household arts and modern manufactures, of the principles of agriculture and bodily processes, and because it opens the mind to the molecular meaning of the marvellous metamorphoses of the visible world." Many portraits are included among the illustrations, which also show the practical side of chemistry in the making of smoke-screens against submarines, the plant for the manufacture of caustic soda, the use of thermite. The student who reads this book carefully and answers the questions at the end of each chapter must gain valuable knowledge.

---

1. *Second Year College Chemistry.* By WILLIAM H. CHAPIN, Associate Professor of Chemistry in Oberlin College, U.S.A. London: Chapman and Hall, Ltd.; New York: John Wiley and Sons, Inc. 1922. Pp. 311. 15*s.*
2. *Second Year College Chemistry; A Manual of Laboratory Exercises.* By WILLIAM H. CHAPIN. Same publishers. 1922. Pp. 115. 7*s.* 6*d.*

1. Though general principles may be introduced into the first year of study of chemistry, they do not usually form the basis of the young student's knowledge. He must first acquire the main facts, on the basis of which general principles can be built. Prof. Chapin in this book recapitulates and enlarges upon the principles enunciated in the first year. He deals with the structure of matter and the kinetic theory, the gas laws, laws of chemical combination, atomic and molecular weights, and leads on to periodic classification, solubility, ionisation, equilibrium. The matter of each chapter is treated shortly and clearly, with some emphasis upon the historical stages by which advance has been made. A little amplification appears to be necessary in some of the chapters, but most of them the student will be able to read and comprehend quite easily. The introduction of theory in the ordinary text-books may become cumbersome, and it is a good plan to have the theoretical portion of the subject dealt with separately.

2. The book on theory is accompanied by a Manual of Laboratory Exercises, chosen to illustrate Prof. Chapin's course of lectures. All the experiments mentioned have been thoroughly tested, and as they are well described students should have no difficulty in working through the course and obtaining good results. The experiments are mainly quantitative and do not need elaborate apparatus. Their performance should promote manipulative skill and encourage the improvisation of means to a definite end. This system of making the practical course connect closely with the theoretical side of the subject is highly to be commended. We find too often that the practical work in chemistry bears no relation to the lecture work, and consequently the latter suffers. Practical work is not stimulating to the student unless it bears upon the other work in hand at the moment. Many of the experiments might with advantage be introduced into the course of the medical student; quantitative work is likely to be more helpful to him as a foundation than the rather aimless identification of unknown substances favoured at present.

JOURNALS.

QUARTERLY JOURNAL OF MEDICINE.—The January number contains the following articles: A Study of Orthostatic Albuminuria by Means of Graphic Records, by James W. Russell. A rapid clinical method for determining small amounts of albumin is described, in which the protein to be estimated is coagulated and the turbidity produced compared with a fluid containing a standard haze, using a Gowers's hæmoglobin apparatus. Hourly estimations were made upon the albumin excretion in cases admitted to hospital as orthostatic albuminuria and mild types of nephritis. In none of the cases examined was the early morning (bed) urine invariably albumin free. In those cases which conformed most strictly with the orthostatic type, standing gave rise to an immediate albuminuria, whereas in the nephritic type there is a postural albumin response, which is not, however, immediate.—The Fractional Test-Meal in the Study of Disorders of the Gastro-intestinal Tract (an Analysis of 174 Verified Cases), by Donald Hunter. The cases reported in this series include ulcers of the stomach and duodenum, carcinoma of the stomach, chronic appendicitis, gall-stones, visceroptosis, and cirrhosis of the liver. In each instance the diagnosis was verified either by operation or by autopsy. The author gives a full account of the gastric contents as revealed by the fractional method of gastric analysis.—Muscular Exercise, Lactic Acid, and the Supply and Utilisation of Oxygen, by A. V. Hill and Hartley Lupton. In this important research into the physical and chemical mechanism of living muscle, the principles already established in respect of the physiology of isolated frog's muscle have been found to hold good in many instances when applied to muscular exercise in normal man. The article is divided into several sections dealing amongst others with the function of oxidation in the body, the rôle of lactic acid in the muscles, heat production, the efficiency and speed of the recovery process, the production of lactic acid in man, and tissue buffer substances. The journal concludes with an account of the proceedings of the Association of Physicians of Great Britain and Ireland at the fifteenth annual meeting held at Oxford last April.

British Journal of Surgery.—In the January number the seventh eponym by Sir D'Arcy Power is on Percival Pott's fracture.—John H. Anderson describes four examples of abnormalities in the duodenum. There was one case each of abnormal shape, abnormal position, constriction due to the superior mesenteric vessels, and to an annular pancreas.—Matthew J. Stewart reports a case in a child of a large myeloid growth in the radius, which was pale throughout. The author always refers to the growth as a myeloid sarcoma (myeloma), illustrating at the same time how obscure is the pathology of these conditions, and how unsatisfactory the nomenclature.—W. Girling Ball contributes an instructive article on the cystoscopic appearances in tuberculosis of the urinary tract, and emphasises their importance in the diagnosis of renal tuberculosis. Thirteen illustrations by Mr. Thornton Shiells add considerably to the value of this paper.—C. E. Shattock records a case of an embryoma of the ovary removed from a child of 2½ years; the tumour consisted of a hydrocephalic fœtal head.—Prof. William Boyd, as the result of research on the strawberry gall-bladder, and on the gall-bladders of animals, concludes that the function of this suspect organ is undoubtedly absorption, and that possibly one of the chief substances absorbed is the cholesterol of the bile. Moreover, in cases of early cholecystitis deposits of cholesterol ester are found in the mucosa of the gall-bladder.—A. P. Bertwistle suggests that much of the value of X ray prints is lost because the outlines of the soft parts are so indistinct, and he has obviated this by filling in the background of the negative before printing.—W. H. Bowen describes his visits to the surgical clinics of Crile and the Mayos, with special reference to thyroid surgery.—A. K. Henry describes a method of approaching the left subclavian artery by performing a costo-transversectomy at the level of the second left rib. Depression of the pleural dome then leaves the artery exposed and quite accessible for ligation.—G. R. Girdlestone reviews 100 cases of spinal fixation in children and adults, and concludes that in the former posterior spinal fixation is seldom, if ever, needed; whereas in the latter it is reliable and of great value.—H. P. Pickerill reports a case of phosphorus necrosis of the jaw.—W. G. Spencer publishes his Vicary lecture on Vesalius: His Delineation of the Framework of the Human Body in the "Fabrica" and the "Epitome."—E. F. Guy has examined 50 patients, by fractional test-meals, on whom a gastro-enterostomy had been performed, and has come to the conclusion that his evidence supports the drainage theory of the operation.—John Morley reports two cases of a congenital cyst of the common bile-duct. The following rare or obscure cases are recorded:—Sir Hugh Rigby: Acute hæmorrhagic pancreatitis due to a round worm in the pancreatic duct. Lieut.-Colonel Novis: A similar case. H. Temple Mursell: Intestinal obstruction from a hydronephrosis in a pelvic kidney. W. G. Spencer: (1) A pelvic hæmatocele in a male, unnoticed until infected from the intestine; (2) endothelioma of the left kidney, extending down the ureter and projecting into the bladder; (3) large intraperitoneal (? parovarian) cyst disappearing after drainage. R. M. Handfield-Jones: Two cases of ruptured sigmoid colon.

Brain. Vol. XLV., Part 2.—Réflexes de Défense, by J. Babinski. This lecture contains a summary of the study of the defensive reflexes, including a criticism of the latest work by George Riddoch and F. M. R. Walsh. Prof. Babinski suggests that the different forms of the reflex—namely, quadruple flexion, triple flexion with extension of the great toe, and flexion of the toes—may be considered respectively physiological, a reflex of primitive defence and an atavistic reflex of attack.—A Study of the Sherrington Decerebrate Animal in the Chronic as well as the Acute Condition, by H. C. Bazett and W. G. Penfield, is an exhaustive research on decerebrate cats; by artificial maintenance of a normal body temperature the cats were kept alive for days and occasionally as long as three weeks. Extensor rigidity is usually maintained, even though the influence of the red nucleus is completely removed. Decerebrate rigidity is considered by the authors as probably dependent on some centre or reflex arc at about the level of Deiters's nucleus. The preparations show no sign of temperature control and never shiver. In the later stages there is a much greater tendency for flexed positions to be assumed. Vocalisation was noted in only 10 of the 124 complete decerebrations; many showed a well-developed mastication reflex. Acoustic reflexes become more brisk after the first few days; glycosuria persists for two or three days and then disappears. In semi-decerebrate animals forced movements were always directed away from the side of removal. The experiments indicated that "the pathway whose interruption is responsible for extensor rigidity decussates in the mid-brain." A condition of increased resistance of the flexor muscles to passive extension, which alternated with extensor rigidity, is described. The authors hold, therefore, that it is possible to speak of two types of decerebrate rigidity.—The Pathogenesis of Subacute Combined Degeneration of the Spinal Cord, with Special Reference to its Connexion with Addison's (Pernicious) Anæmia, Achlorhydria, and Intestinal Infection, by A. F. Hurst and J. R. Bell. The authors maintain that the achlorhydria is an essential predisposing cause of the anæmia and also of the subacute combined degeneration of the cord, by allowing unchecked infection of the duodenum by organisms swallowed from the mouth. They recommend that a drachm and a half of diluted hydrochloric acid in six ounces of water should be taken at each meal, in addition to rigorous measures for removing oral sepsis and vaccines.—The Meningiomas (Dural Endotheliomas): their Source and Favoured Seats of Origin, by Harvey Cushing. The author traces their origin to cell clusters formed by proliferation of the endothelium of the arachnoid villi. Such proliferation has been shown to occur when the villi are experimentally blocked by particulate matter; under certain circumstances, obscurely related to the genesis of tumour formation in general, some of the cell clusters show neoplastic tendencies. The meningiomas are shown to occur in connexion with the dural venous sinuses with which the villi are also in relation.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 24, 1923.

THE MYSTERY OF MAN.

THE man to whose distinguished lot it falls to be invited to deliver the Hunterian Oration before the Royal College of Surgeons of England may be embarrassed as well as flattered. JOHN HUNTER can be described as the patron saint of surgery, as we now understand the art and science, while the College which enshrines his museum may, with little exaggeration, be termed his temple. Surgery, as built up by the wisdom and learning of HUNTER'S forerunners, was placed immediately upon a different plane by his theories and his practice, by his enormous generalisations and his relentless devotion to details, by his far ranges of study and his close concentration upon the central scheme which his researches laid bare before him. HUNTER was primarily a practical worker, and the weak spot in his equipment was his unequal and misty method of exposition. A long line of followers have delivered to his College an Oration in his honour, and have found their texts, now in some phase of HUNTER'S multifarious work, now in the fulfilment of a striking prediction, now in the moral to be drawn from his passionate and inspired researches; and many of these addresses have been examples of that literary gift which HUNTER did not possess, or did not cultivate. In this way, and often splendidly, the Hunterian Orations have filled gaps in the Hunterian prophecies.

It can therefore be well understood that to-day the Hunterian Orator must wonder what remains to be said about a saint so definitely canonised and so assiduously celebrated. Some of the embarrassment of these orators has before now communicated itself to their audiences, but Sir JOHN BLAND-SUTTON'S Oration, which was published in our columns last week, betrayed no doubt as to the manner in which his tribute would be paid, whilst he elicited from the audience, as well as the reverent attention due to a memorial address, the unusual and yet perfectly natural concomitant of laughter. He narrated simply the events of HUNTER'S life, and showed that the mainspring of his wonderful performances was the readiness to use opportunity. HUNTER'S magnificent curiosity urged him forward upon different tracks. His early lessons as a handicraftsman he applied as a dissector; what he learned as a dissector he utilised as a biologist; and the results of his biological investigations became the foundation of modern surgery, viewed as a grand development of anatomy and physiology. In telling the story BLAND-SUTTON revealed how veritably HUNTER had been to him a patron saint, a saint with whom he, like any mediæval monk, could joke while paying him reverence; he had followed his leader's footsteps geographically as well as mentally, and was able to illustrate the meaning of HUNTER'S many-sided activities by examples drawn from the learning of to-day, the results of refined and intensive observation quite impossible to the investigators of the eighteenth century. And in so doing the Hunterian Orator preached, unwittingly or no, a doctrine of the finest hope, for every word of his studiously simple address conveyed the lesson that the study of natural science is reinforced from every source, and that all our philosophy, learning, poetry, and religious faith may well be aspects of the same synthetic truth.

At the Festival Dinner held at the College after the delivery of the Oration, Mr. RUDYARD KIPLING approached the subject of JOHN HUNTER through the medium of BLAND-SUTTON'S words, and everyone should study the great author's tribute to the part played by medicine in interpreting the mystery of man. "Man," said KIPLING, "the imperfectly denatured animal, who cannot trust the evidence of his own senses in the simplest matter of fact; whose evidence on the simplest matter is coloured by his own iniquities; Man, always the hunter, went up against the darkness that cloaked him and every act of his being, to find out what order of created being he might be. He called it scientific research. It was the old quest under a new name. But, this time, the seekers who headed it, unlike the Priest and the Lawyer, admitted that they knew very little. Experience had taught them to be humble. For that reason their knowledge was increased." No sweeter or truer words could have been used to describe the leaders of scientific research. To probe, to question, and to doubt have comprised their duty; but discharge of that duty, when faithful, has compelled them to be humble in the presence of the vast revelations which have followed, and to-day, at least, they are willing to learn from and ready to coöperate with the philosopher, the divine, and the poet in the discovery of the grand synthesis, the nature of man.

◆

THE PRESENT POSITION OF PSYCHOTHERAPEUTICS.

THE general interest aroused in the theory and practice of psychotherapy, partly as a sequel to the experiences of the late war, partly as the expression of a steady tendency, observable in other departments of medicine as well, towards a rational as opposed to a symptomatological therapeusis, shows no sign of abatement. Willing or no, the practitioner cannot escape a subject which is fastened on at intervals by editors of newspapers for topical if superficial discussion, which provides material for debate at societies not ostensibly scientific, which his patients themselves will bring to his attention should he essay an attitude of ignorance or indifference. In a matter of this kind it is desirable to preserve at least some semblance of perspective. Psychotherapeutic activity has never, in reality, been under any cloud for at least half a century. The opposition engendered by the pioneer work of JAMES BRAID—to mention but one name out of many that have adorned the record of a hundred years—has long since vanished; scientific research, coupled with successful clinical application, has in fact been abundantly manifest from the days of CHARCOT. Schools of psychotherapy have waxed and waned, no doubt, but the effect has been gradually if imperceptibly to leaven the lump of professional unconcern and agnosticism. Of the forward impetus provided by the labours of JANET, FREUD, and JUNG, there is no need to speak; it suffices to allude merely to new journals, new books, new societies and clubs, new hospital appointments, new medical school tuition, to indicate in a sentence the gigantic strides made by a "new" psychological movement.

For good or ill, this ever-growing interest in the things of the mind, physiological and pathological, must be taken as a sign of the times. However violent in some quarters the resistance to Freudian doctrine, however unsatisfied the critical mind in respect of not a few of the pet contentions of the "wild psycho-analyst," however impatient the conservative physician of the broad-casting of psychological jargon and psychotherapeutic method among the laity, the situation now is such that the current can no longer be withstood; it may only be guided. Far beyond the strict limits of the medical profession the echoes of the blows struck at an academic and scholastic psychology are still reverberating; it is no exaggeration to say there is scarcely a department of intellectual activity that has not felt the revivifying touch of a method of investigation based on the exploration of mental arcana hitherto more or less tacitly regarded as inaccessible. With such a rush of enthusiastic research by ardent apostles of a twentieth-century "revival of letters," it is little wonder that the coldly critical are brushed aside. The sceptic may justifiably point to the history of popular movements of the past, which have had their day and ceased to be. He may recount, to his own satisfaction, the story of ill-regulated and exploded "psychotherapy" as instanced by the enormous though transient success of Dr. Elisha Perkins's metallic tractors, of this and that quack of other years whose name was for the time enshrined in the honour of an "-ism," just as—so he will have it—we speak of "Freudism" to-day. But the analogy is valueless, or, rather, paradoxically, is capable of conveying an instructive lesson. Grotesque as has often enough been the particular means employed to influence the illiterate and gullible, no one can deny the actuality of many cures thus effected by irregular practitioners, whose only claim to distinction has frequently been an inborn genius for ascertaining what their public have been looking for. Not otherwise can we explain the furore attending both older and newer exhibitions of psychotherapeutic skill by some who have little insight into their own powers, who, indeed, may have been exercising them unconsciously. The one conclusion to be derived from the unbiased study of these popular nostrums and their advocates is that there has always been an immense amount of minor and probably also of major complaint relievable by mental technique. This is the lesson taught by the history of quackery and charlatanism, or, in other instances, of genuine psychotherapy blundering and masquerading under the guise of the latest novelty in panaceas. Human nature remains much the same, as do the ills to which flesh is heir, hence we cannot be surprised at the throng besieging the portals of the skilful lay practitioner of suggestion, for in this respect history is merely repeating itself. The medical profession, however, is sadly to blame in having persistently failed to take cognisance of the import of these sometimes startling successes; instead of looking askance at any variety of healing outside the pale, it should have seized on the principle of learning from the enemy and should have seen to it that the coming generation of medical men were instructed in the art of psychotherapy. Clearly he is best provided with therapeutic resource who is also equipped with a technical knowledge of disease and of ailment, and who can distinguish and diagnose ere application of mental methods is resorted to. For every reason, then, the curriculum of the future should and must include at least a modicum of psychotherapeutic theory and technique.

We are glad to note the discussion on this subject at the Medical Society of London, reported elsewhere in our present issue. In respect of most of their audience, doubtless, the advocates of psychotherapy who took part were forcing an already open door; others, it may be, were somewhat chary of committing themselves to methods of which it may be considered the value is not yet proven. However justifiable this attitude of reserve, in certain respects, the general truth cannot possibly be assailed; "Freudism," suggestionism, hypnotism, are not the scientific fads of the hour; slowly but surely the basis on which their working is erected is being laid down, the mechanisms of the mind are being exposed, the influence of the mind over the body is being determined, and if exactitude is not quite attained it is nevertheless within reach. "The real physician is the one who cures," it has been said; "the observation which does not touch the art of healing is not that of a physician, it is that of a naturalist." Psychotherapy is open to large abuse, and has therefore been assiduously decried ever since it became an art; if it is to take the place it deserves among recognised methods of treatment this will only be by its formal study and deliberate employment by the medical profession. The responsibility must be shouldered; else ailing humanity will turn, as often before, to the man who can cure, whatever his qualifications, and will desert those whose training and knowledgableness should fit them best to minister to the mind diseased.

MEDICINE'S DEBT TO RÖNTGEN.

The discovery of X rays by Prof. v. Röntgen proved of momentous importance to physical science, for it led to the discovery of radio-activity in the following year, and introduced physicists to a new type of radiation whose place in the electro-magnetic spectrum was only finally established in 1913. It is sometimes asserted that we do not know the nature of these rays; it would, perhaps, be more appropriate to say that we do not realise their nature. That they are electro-magnetic radiations akin to light, differing only from the latter in having a much smaller wave-length and correspondingly greater frequency, can hardly be doubted, for measurements upon their wave-length are now carried out in many laboratories with an accuracy of one part in a thousand; but a long familiarity with such rays may still fail to make the user realise that the wave-lengths in question are of the order of a ten-millionth part of a millimetre, and that they follow one another with a frequency of about a million billion per second. Röntgen was, in the first flush of his discovery, inclined to think that the X rays were longitudinal vibrations of the ether, but the idea was not upheld. Röntgen had a long career in physics before he made the discovery, when he was about 50 years of age, which was to bring him world-wide fame. As early as the year 1878 he published work upon the conditions which regulate the passage of electrical discharges through gases at different pressures, but there seems little evidence that the discovery of X rays can be directly linked with these early measurements, nor can we point to any detailed work upon the study of gas discharge by Röntgen which paved the way for the final achievements. All this was done by others, notably by Plücker, who discovered the cathode stream as early as 1859, and by Crookes, whose life-long studies upon the nature of the electrical discharge through rarefied gases led him to the view that the cathode stream was a "fourth state of matter." The discovery by J. J. Thomson, in 1897, of the true nature of the particles, or corpuscles, as he called them, constituting the cathode stream justified to the full the attitude of Crookes in differentiating them from any of the usual phases of matter. There was much information which lay to hand when RÖNTGEN resumed work upon the electric discharge through gases. It would seem quite wrong to call the discovery which ensued accidental, for it was the result of careful observation following upon well-arranged experiments. But it is amazing to think how close upon this path of discovery others must have trodden.

It is difficult for those whose experience of our profession is recent to realise the change brought about by the application of X rays to medical practice. Since RÖNTGEN'S discovery was made public in December, 1895, there has been a progressive advance in its medical utilisation which has largely corresponded with, and has been made possible by, the contemporary improvements in technique. Very little time was allowed to elapse before the new discovery was put to a practical test as a means of diagnosis. In an interesting historical note,[1] Dr. H. A. COLWELL says that within a week of the first demonstration of X rays COX, of McGill University, Montreal, so successfully localised a bullet that had been in a patient's leg for six weeks that it was removed next day. The first X ray photograph in this country was taken[2] by Mr. A. A. CAMPBELL SWINTON, an electrical engineer, of his own hand on Jan. 16th, 1896, with an exposure of 20 minutes, and a week or two later an apparatus was at work in THE LANCET Laboratory. As showing how greatly the technique has now improved reference may be made to two companion skiagrams of the hand, in Dr. G. W. C. KAYE'S recent book,[3] one taken in 1896 with the 20 minutes' exposure and conveying comparatively little information, the other by Dr. ROBERT KNOX in 1921 with 1/100 second exposure, which is like a photograph of the dry bones. Investigation on these lines was extremely active in many medical centres in January, 1896, notably in Vienna by MOSETIG in Exner's Institute, and in Paris by LANNELONGUE. Sir OLIVER LODGE, in February, 1896, published a skiagram of a gunshot wound, and in the same number of the *British Medical Journal* a fracture of the finger was recorded from St. Thomas's Hospital; in March an investigation into the detection of urinary and biliary calculi, which had been introduced into the body of a dead monkey, was described in THE LANCET; at the conversazione of the Royal Society in May, the late SIDNEY ROWLAND, who had made a number of reports on the subject to the British Medical Association, exhibited 50 skiagrams; and the following September, in his presidential address to the British Association at Liverpool, Lord LISTER touched on the help that was thus rendered to surgical diagnosis. Earlier in May of this same year MACINTYRE, of Glasgow, took skiagrams of the soft parts, including the heart, and thus initiated the now familiar diagnosis of aneurysm and other intrathoracic lesions. The use of X ray bismuth meals in the diagnosis of gastro-intestinal disease and in pyelography (1906) were most valuable developments in diagnosis; more recently[4] the detection of gall-stones with greater accuracy and frequency has been a distinct advance, and within the last few years the method of introducing oxygen into the peritoneal cavity, in order to facilitate the definition of the abdominal contents, has been of further assistance in clinical diagnosis. Prof. JACOBÆUS'S thoracoscopy under the X ray screen enables pleuritic adhesions to be divided by the cautery, and thus both improves the outlook in cases of artificial pneumothorax and serves as an earnest of the future that lies before a combination of X rays and special forms of surgical treatment.

From such a brief sketch it is obvious that the introduction of X rays as a means of physical diagnosis is an advance comparable with that due to the assistance of the microscope in pathological anatomy. Equivalent to another sense it has thus become an invaluable means of confirming, correcting, and extending the conclusions derived from the ordinary methods of physical diagnosis. There is, indeed, a danger that its use in hospitals may lead students to neglect the ordinary methods of physical diagnosis which may be the only means available to practitioners in remote country districts. Not only has it revealed the living anatomy of the body, and in the case of the stomach greatly altered our ideas of its normal position, but it has thrown light on the physiology of the hollow viscera by showing their movements. The knowledge thus obtained of the normal anatomy and physiology of the abdominal viscera has been mainly, but perhaps not entirely, due to the stimulus of the needs of medicine and surgery; F. H. WILLIAMS, of Boston, appears to have begun the use of bismuth meals in 1899, but years passed by before this method came into general use, and it is interesting to note that in 1898 W. B. CANNON, when a student at Harvard, studied the movements of the stomach by means of X rays. About the therapeutic uses of radiations much remains to be ascertained, but that a very powerful agent is thus available there can be no doubt. The ill-effects of X rays became noticeable in the first year of their medical use and led to early therapeutic use as depilatories; their application has since been extended in other directions by dermatologists. The influence of X rays on new growths has long been exhaustively studied both experimentally and in practice, though the limitations of this remedy and of the intensive Erlangen treatment still await a final decision. The autolytic effect of X rays on the tissues has also been utilised in the treatment of leukæmia, of exophthalmic goitre, and of metrorrhagia, by acting on the bone marrow, the thyroid, and the ovaries respectively. But up to the present time it remains true that the value of X rays is better established in diagnosis than in treatment, and it is in respect of diagnosis that their discovery has so largely changed our outlook on medicine. To realise this it is only necessary for a surgeon to picture how he would deal with gunshot wounds, and the physician how he would diagnose thoracic and abdominal lesions, without X rays.

◆

THE TREATMENT OF DIABETES BY INSULIN.

WE have received from the Medical Research Council a further statement regarding the steps which are being taken in this country for making insulin available as rapidly as possible for the treatment of diabetic patients, under suitable guarantees of authenticity, potency, and safety. When the last public communication was made in November, 1922 (THE LANCET, 1922, ii., 1081), the methods of producing this substance were imperfect and necessarily wasteful, and its use in the treatment of disease was, and indeed is still, in the experimental stage. The Council are now able to report that rapid and satisfactory progress has been made as a result of research work which has been undertaken at various centres in this country in confirmation or extension of that already accomplished in the University of Toronto. Members of the Council's scientific staff at the National Institute for Medical Research, Hampstead, have endeavoured to increase the yield of product from the raw material, to simplify, shorten, and cheapen the processes of its production, to obtain accurate measurements of potency by reference to a fixed standard of value, and finally to find the best methods of securing the bacteriological sterility of the final product. In all these directions important progress has been made. Those working for the Council have been in constant touch with the workers at Toronto, and they have both received and given full information of new developments and improvements as they have occurred. The results obtained have been made freely available for the assistance of those engaged in the other work to be mentioned below. Technical information and small samples of finished product have, so far as possible, been put at the disposal of approved scientific workers undertaking collateral lines of investigation elsewhere.

[3] Practical Application of X Rays, 1922.

[4] L. G. Cole (1914); J. T. Case; R. Knox.

At various hospitals where the necessary facilities existed for biological and chemical work in the laboratories, and for scientific clinical studies, investigation and carefully controlled treatment under suitable safeguards have been undertaken in close association with the work of the National Institute. Insulin is being produced, standardised, and used in treatment for the relief of patients selected for the purpose at each of the following hospitals: in London, at St. Bartholomew's, Guy's, St. Thomas's, the London, and University College hospitals; in Sheffield, at the University Departments of Pharmacology and Physiology and the Royal Infirmary; in Edinburgh, at the Royal Infirmary. Arrangements are in progress for extending this work to other hospitals and institutions, where the necessary conditions, both personal and material, can be provided. The Council, lastly, have made at the same time every effort to accelerate the production of insulin upon a manufacturing scale. Experience in Canada and the United States has already shown the difficulty of passing from the small laboratory scale of production to large scale production by mechanical means, without which the product can never become generally available at reasonable cost. The Council have been in communication throughout with certain manufacturing firms in the several parts of the country with whom the Council have entered into agreements securing in the public interest a control of the safety and potency of the product and its sale at a fair price. The Council have given at the same time every assistance at their disposal by way of information likely to accelerate satisfactory production. In the promotion of manufacture by particular firms it has been necessary to consider the distribution of the available raw material and the special technical difficulties attending its collection and proper use. No royalties are payable to the Council under any of these agreements.

The Council are able to say that the progress towards successful large scale production has been more rapid than they had ventured last November to hope. This has been due equally to the laboratory investigations at the National Institute already mentioned and to the experience, skill, and enthusiasm which the firms have shown in their coöperation with the Council. The Council believe that, subject to limitations of raw material in particular districts, successful manufacture is now assured; but a period of some weeks must pass before laboratory tests and clinical use under special safeguards will have made it justifiable for a supply to be issued generally for routine use under the ordinary conditions of medical practice.

Inquiry into Results of Gastric Operations.—The Scottish Committee of the British Medical Association has decided to institute an inquiry into the ultimate results of the operations of gastro-enterostomy and gastrectomy, and has appointed a special committee for this purpose, of which the convener is Mr. D. M. Greig, Edinburgh. Local committees will be formed in each of the four university centres to assist in the collection of data, the aim being to try to obtain complete histories of a number of cases, and to see what general conclusions may be drawn from their examination.

Annotations.

"Ne quid nimis."

THE MEDICAL OFFICER OF HEALTH.

William Farr, one of our greatest medical statisticians, prophesied in 1875 that the national standard for mortality rate was capable of considerable diminution. Farr's predictions were not and could not be based on any betterment in his time in the rates of mortality for the whole population. There would have been no ground for optimism. His faith in the future, so far as its justification was merely arithmetical, was inspired by inter-local comparisons. He pointed out, for instance, that while in "healthy" districts there was an annual mortality per cent. of boys under 5 of 4·2 and of girls of 3·5, the corresponding rates in Liverpool were 14·4 and 13·4. In an interesting address to the Society of Medical Officers of Health on Feb. 16th Dr. Major Greenwood put forward these points, and showed that from such inter-local comparisons we might still derive inspiration. Dr. Greenwood proceeded to consider to what extent the future course of mortality rates could be predicted from the available data by mathematical means, and gave technical details of the methods most likely to obtain useful results. The detailed results of a study by these methods of the course of mortality rates at different age-periods for each sex for Lancashire, London, and the South-Western counties respectively led to two conclusions: The first, and the most sombre, was that upon the sole evidence of the national rates of mortality no prudent man would stake money on the chance that the rates of mortality of adult males between 45 and 65 would decline much further. The second and more hopeful was that when rates of mortality in two great industrial areas differed by so much as 20 per cent.—as in the London and Lancastrian males, aged 55–65—the faith which inspired Farr should encourage and strengthen us. It was hard to believe that racial, industrial, or climatological differences made so great an inferiority in the north-western manufacturing area inevitable. Dr. Greenwood next considered the change in our mortality rate from enteric. He contended that the triumphs in this respect owed nearly everything to the epidemiologist, so far as the civilian community in peace time was concerned, while paying a tribute to the bacteriological work which had been the saving of thousands of lives under conditions when water and food supplies could not be shielded from contamination. It might even be that if antityphoid inoculation had been discovered in 1860 our present position would have been far worse. Simon and Farr did not stay to consider whether it might be possible to immunise the population against typhoid; they said there ought not to be any typhoid at all, and worked to that end. Dr. Greenwood spoke also of the diseases responsible for the excessive mortality of later adult ages, which were unfortunately for the most part diseases which the medical officer of health considered to be outside his sphere of action. He concluded by a reference to the psychological factor, especially in so far as it concerned the tedium of life to the middle-aged. Dr. Greenwood ended with what he termed his rashest prophesy, that when the medical officer of health was a psychologist, as well as a bacteriologist, a legal expert, a eugenist, a statistician, and all the other things he was now, we should see a further decrement of mortality at the most unpromising time of life.

DISTEMPER RESEARCH AND COMPARATIVE MEDICINE.

The lack of active coöperation between human and veterinary medicine has been recognised for some time as constituting a serious reflection on both branches of the curative profession. Disease is ubiquitous in the animal kingdom, and the artificial limitation of the study of morbid processes by species or genera is as illogical as it is inimical to progress. A movement which should lead to a valuable development of comparative pathology is that exemplified in an appeal being made through the press, headed by the *Field* and enthusiastically welcomed by the *Veterinary Journal* and canine press, to obtain funds for a prolonged and earnest research into the question of disease known as "distemper" in the dog. Numerous attempts have been made in the past both by medical and veterinary scientists to discover the causal organism of distemper, with a view to finding a preventive or curative treatment which can be relied upon. Up to the present these attempts cannot be said to have met with much success, and it is suspected that the cause of distemper has its origin amongst those which are at present classified as the ultra-visible viruses. If this is proved to be the case the path towards the elucidation of certain human diseases will have been cleared of sundry obstacles to progress. An influential committee, consisting of masters of hounds and leading men in the medical and veterinary professions, have associated their names with this appeal to the public for funds, and those interested are asked to subscribe annually for a minimum period of three years. Reports are promised to subscribers at stated intervals. The appeal is likely to meet with an enthusiastic response. There is no disease of the dog which is of more importance than distemper on account of the high direct mortality and of the complications and sequelæ which follow in its train. No disease is more disappointing to treat, and the case which begins mildly is as likely as not to end with the most serious result. It has been compared with measles in the human subject, but probably epidemic influenza forms a better analogy. Acute prostation, marasmus, pneumonia, dysentery, jaundice, epilepsy, meningitis, chorea, and paralysis are only a few of the terrors which the veterinary surgeon has in his mind when called in to treat a case of distemper. Distemper is a disease in which good nursing and invalid dieting are particularly necessary. Unfortunately, the various vaccines and sera which have been tried up to the present give little better results than much-advertised quack remedies and so-called distemper cures, which extract money from the pocket of the distracted owner of a favourite dog and give him practically nothing in return. We commend the proposed research to all lovers of dogs as well as to those interested in veterinary research mainly on account of its bearing on medical problems.

STEINACH'S OPERATION.

IT must be obvious to all who have studied the literature of Steinach's operation that most writers who attempt to explain its rationale become more than a little nebulous and dependent on highly speculative hypotheses. The subject is one with an apparently irresistible appeal to elderly persons whose waning virility renders them disconsolate and fretful. A paper has recently been published by Dr. Knud Sand, of Copenhagen,[1] in which he discusses rationale, technique, and the results he has obtained in 18 cases. Vaso-ligature, he points out, is intended to cause degeneration of the spermatic epithelium, "an atrophy of the whole spermato-generative tissue, and subsequently, gradually, often perhaps after a very long time, a hypertrophy of the Leydig cells—i.e., the hormonic tissues accompanying this atrophy." The account of the operation is more lucid and informative than that of the rationale. It is not enough to perform high vasectomy, nor even to resect the vas at the level of the cauda; epididymectomy is required, and must be performed with the greatest caution. Close to the caput, several centimetres of the epididymis are exposed by small instruments, the greatest care being taken not to injure the small vessels and nerves on which the nutrition of the testicle depends. After isolation, the section of the epididymis to be removed is clamped at either end by Kocher's forceps. After resection, the free ends are firmly ligatured and then cauterised to ensure cicatricial collapse. The whole operation can be performed under local anæsthesia through a small incision. Dr. Sand classifies his cases according as they showed signs of senile decay or other diseases such as depression. His detailed records of every case suggest that the pathological changes indicated by the symptoms must have been remarkably varied. So, for the purpose of a scientific experiment, these cases were highly unsuitable, and we would refer readers to the original, which is published in English, for particulars. But it may at once be pointed out that in no case did the patients complain of any bad results. Most of them were pleased—some very much pleased—with the results. The observation period was from 3 to 21 months, and in some cases the desired effect did not occur till about half a year after the operation. Dr. Sand concludes that epididymectomy is a harmless operation which, in cases of senile decay, impotence, and depression may, in a great number of cases, prove strikingly beneficial. In one of his cases the patient was cured of a depression which had lasted for many years, and in several cases there was an increase of weight and nimbleness. Though Dr. Sand is an ardent advocate of the operation, and has had considerable experience, the method is evidently in such an early, experimental stage that its unreserved advocacy is not at present warranted.

FURTHER EXPERIENCES WITH BAYER "205."

RECENT numbers of the *Archiv. für Schiffs- und Tropen-Hygiene* have contained interesting details of further work on the new synthetic vermicide Bayer "205," showing the possibilities and limitations of the remedy. In the issue for October, 1922, Prof. W. Mollow, of Sofia, reports a case of kala-azar contracted by a Bulgarian prisoner of war in Greece. Taken prisoner in September, 1918, he was in Larissa in June, 1919, when he and several of his fellow-prisoners had to go to bed with a fever (from which the Greek population seemed also to suffer), for which they took a great deal of quinine without benefit. However, by the summer of 1920 he had recovered and reached home in that November well, but without appetite. Ten days later he again suffered from shivering and pyrexia, which again persisted in spite of quinine. In January, 1921, he noticed that his spleen was enlarging and becoming painful. In February he bled frequently from the nose and gums, and small hæmorrhagic lesions appeared on the legs. He gradually became bedridden, the spleen enlarging as the rest of his body wasted. Small painful papules appeared on his face, arms, and legs, breaking down into chronic ulcers. In July (1921 probably) he was taken into hospital, when it was noted that he was anæmic; hæmoglobin, 30 per cent.; red cells, 2,550,000; white cells, 2500; polymorphs, 75 per cent.; lymphocytes, 25 per cent. There was a trace of albuminuria; there were no casts. The long history of pyrexia uninfluenced by quinine, the notable enlargement of the spleen, the hæmorrhages, the ulcers, and the cachexia caused the disease to be regarded as kala-azar. On August 13th he was given intravenously 0·2 g. of Bayer "205," the rest of the solution at the time prepared being given to another patient who suffered no inconvenience. This patient, however, shivered 20 minutes later, and in two hours had bleedings from the nose and gums, vomiting, and bloody stools. He said he had frequently had similar attacks, though none so severe. Ultimately his heart failed, and he died at 4 A.M. It was supposed that the patient was too weak to stand the injection. Leishmania were seen in the blood from the spleen taken immediately after death. At the post-mortem, 24 hours later, they were found only in the bone marrow. The spleen was 12½ inches long and weighed 6 lb., and there was peritonitis on the posterior and anterior surfaces, with small abscesses here and there.

In the November issue Dr. Migone and Dr. T. Osuna, of Ascuncion, in Paraguay, describe the eminently successful results obtained by the use of

---

[1] Acta Chir. Scand., Dec. 22nd, 1922.

Bayer "205" in the curative and prophylactic treatment of the trypanosome disease, mal de caderas, among the horses on the great ranches of Paraguay. They, in the first place, insist that it is essentially necessary for every large farmer to have someone by him skilled in the use of the microscope, to be able to detect the disease in the early stages by recognising the trypanosomes in the blood. Histories are given of horses slightly affected and of horses practically dying, which were cured by the injection into their veins of 2, 3, and 4 g. in a 10 per cent. solution in normal saline at weekly intervals. The horses recovered and became fit for work. Some were even sold. They did not relapse. Two grammes is a prophylactic dose. The very carefully observed results have turned out so well that mal de caderas, which formerly decimated the ranches, may now be said to be under control, so that a new and happier future has opened before the stock breeder.

A FALLING CANCER DEATH-RATE.

So much has been written in the last 20 years or so on the progressive increase of the mortality from malignant disease that it is encouraging to come across an instance where the rate appears to have indubitably diminished. Dr. W. T. Howard has made a close study[1] of the deaths from cancer in Baltimore for which data of some kind are available since 1813. He points out that the mortality is negligible before the fourth decade of life, and is always higher in whites and females than in coloured people and males. Between 1830 and 1920 the proportion of people over 30 and over 40 increased by 55 and 75 per cent. respectively, and since 1860, and especially since 1880, the relative number of negroes has decidedly declined—facts which would to a large degree account for the large recorded increase in crude cancer mortality. Taking these factors into account, he then shows for the breast and uterus—two cases where improvements in the diagnosis of fatal cases cannot have had much influence—that the mortality has definitely fallen in the last 30 years. Rates specific for age and sex for the breast remained stationary from 1880 to 1910 and fell by 25 per cent. in 1920; for the uterus there was a substantial increase from 1880 to 1890, but since then the rate has progressively fallen and in 1920 was 40 per cent. less than in 1890. There is no evidence bearing on the question whether this decrease is due to a fall in the incidence of cancer or to improvements in its treatment; Dr. Howard inclines to the latter interpretation, which may well be correct in a city so well provided with progressive medicine. But it would be equally legitimate to propose that general improvements in habits of life have resulted in a smaller occurrence of cancer or have enabled the natural defences of the body to obliterate a larger proportion of malignant tumours in their early stages.

MENTAL DEFICIENCY AND SOCIAL FAILURE.

THE methods used for the diagnosis of mental deficiency are still more or less tentative, and all experimental work that will tend to greater accuracy is to be welcomed. The ultimate criterion of mental deficiency is, of course, "social inefficiency," but this is not diagnosable with absolute certainty until some serious social failure reveals it, and the diagnosis is then too late. The problem before the certifying officer is that of making a prognosis of future social incapacity in early life on the basis of the present condition of the person before him. Dr. J. Marius Moll's "Report on Mentally Defective Children in Transvaal Government Schools" for 1919–20—somewhat belated in appearance—deals mainly with this problem, and it would be well if all Government and municipal reports of this class could show so good a record of useful experimental work. As he points out, it was for a time thought by some that the intelligence quotient based on Binet tests was going to solve the problem, but instead of providing us with a definite borderline separating the normal from the subnormal, it only gives us a shadowy borderland area, peopled with cases that we hesitate to call feeble-minded, but who may be the most dangerous of all socially. In addition, persons of low intelligence quotient do not infrequently turn out to be social successes in their own limited sphere, while persons of relatively high intelligence quotient may behave in a manner that no society can tolerate, and be impervious to society's demands. Social failure, in fact, frequently depends upon qualities of character and temperament, and for these things satisfactory tests are lacking. A moderately low intelligence quotient, too, may go along with quite a useful amount of industrial capacity, which will fit its possessor for mechanical routine employment.

Porteus claims for his maze tests that they give a very good indication of both social and industrial efficiency. Dr. Moll has not used them sufficiently to endorse this claim, but he has himself experimented with certain tests of Healy, and of Pintner and Patterson with a view to the estimation of industrial capacity, and this report is largely a record of his results. He has endeavoured to standardise the tests, showing by graphs the degree of attainment or the length of time taken at each age—graphs derived from examination of 700 normal and 400 subnormal children. The most perfect result was obtained with Healy's pictorial completion test, but all show a more or less uniform progress from age to age. Dr. Moll is of opinion that a combination of the Binet tests (preferably in the Stanford form) with the Porteus and some of these "mechanical" tests gives a good basis for diagnosis—supplemented, of course, by allowance for physique, heredity, home conditions, and social conduct already observed. This report is a valuable contribution to the now considerable literature of the subject.

CARBON-MONOXIDE POISONING.

THREE cases reported by R. Jaksh-Wartenhorst,[1] of Prague, illustrate some of the peculiarities of carbon-monoxide poisoning. The patients were brought to hospital at the same time, from the same dwelling-house: two women, aged 33 and 19 respectively, and a man aged 21. In all three carbon monoxide was found in the blood, rendering the diagnosis certain. The temperature was raised in all, in one case to 38° C. at first, dropping the next day and remaining subfebrile except for a rise to 38·9° on the twenty-third day. The second case had a temperature of 39·8° C. the day after admission, falling the day after to 38·2° and settling to normal on the fifth day. The third case was admitted with a temperature of 40·3° C. which dropped the next day to normal, and did not rise again. It is well known that the temperature in carbon-monoxide poisoning tends to rise when lung complications are present, but in these cases the lungs were free, and therefore it is demonstrated that the human organ reacts to this poison with a definite rise of temperature, thought by Jaksh-Wartenhorst to be due to a microscopical hæmorrhage in the region of the heat centre. The blood pressure in the first and third cases rose to 120 and 140 mm. Hg, while that of the second case sank to 90. In all the cases the blood picture showed similar changes; a slight increase in the red cells, and a marked leucocytosis (with 80 per cent., 95 per cent., and 80 per cent. polymorphonuclear cells respectively) which lasted well into convalescence. Thus, the first case had 22,000 leucocytes the day after admission, and 12,000 25 days later; the second case had 22,600 at first and 29,200 27 days later, while the third had 16,000, falling to 10,000 seven days after. Glucose was found in the urine for some hours after admission, but was absent the next day, and in only one case could alimentary glycosuria be produced four days after the onset. Apart from traces of albumin in two cases and transitory acetone in one, no urinary changes were noted. The nervous symptoms were remarkable in that with the same poison very variable manifestations were observed. All three cases were deeply unconscious on admission, with stertorous breathing, and they all showed signs of severe cerebral irritation. Thus, in the first case alternating right- and left-sided convulsions occurred, lasting up to two hours, with intervals of 5 to 10 minutes. During the convulsions the respirations appeared to cease, and in the interval they were Cheyne-Stokes in rhythm. The convulsions persisted for 24 hours, and the following day a flaccid paralysis of the right arm and leg became apparent, thought by Jaksh-Wartenhorst to be due to a hæmorrhage into the internal capsule caused by weakening of the blood-vessel walls by the action of the carbon monoxide. The paralysis gradually improved until, when the patient left the hospital 31 days after admission, only a slight weakness of the right arm was present. Two months later the patient attended the hospital again, suffering with a recent gonorrhœa. He then had an intention tremor of the right arm and leg, slight ataxy, and exaggerated tendon and periosteal reflexes. The second case was characterised by trismus and opisthotonos, which came on in spasms resembling tetanus. In the intervals Cheyne-Stokes breathing was present. Retinal hæmorrhages were present in this case. The third case showed also tetanus-like convulsions, but they were unilateral, lasting 5 to 10 minutes, during which respiration stopped. Cheyne-Stokes breathing was also seen in the intervals. The convulsions ceased in 24 hours, but started again on the second day after admission, accompanied by deep coma which lasted until the third day, when the patient woke up fully conscious. It will be noted that all the symptoms were those of temporary cortical lesions, and may have been due to the action of the carbon monoxide on the vessels. All three cases recovered, and in only one were any after-effects noted—namely, the weakness of the right arm already mentioned. The treatment carried out in the three cases was the same — venesection, saline transfusions, cardiac stimulants in the form of caffeine, digitalis, and in two cases of threatened cardiac failure intravenous strophanthine.

CHARLES WHITE.[1]

THAT famous Manchester practitioner, Dr. David Lloyd Roberts, who died some two years ago, founded a lectureship in connexion with the Manchester Royal Infirmary, characteristically leaving the choice of lecturer to those who were administering the trust and the choice of subject to the lecturer, with the provision that it should be on "any subject of medical or scientific interest." Accordingly, the first Lloyd Roberts lecture was delivered by Prof. Adami, Vice-Chancellor of the University of Liverpool, who took as his subject "Charles White, of Manchester, and the Arrest of Puerperal Fever." Prof. Adami set out in his lecture the claims of Charles White, pupil and friend of the Hunters, to be one of the great obstetricians of the world, and a forerunner of Semmelweis in establishing the true nature of puerperal fever. He analysed White's teaching, and suggested that much of it is again coming to the fore after a lapse of over a century, while he proved that 70 years before Semmelweis's famous work White had indicated that "child-bed women were liable to putrid fevers" owing to the general insanitation of their environment. Prevention of self-infection in puerperal cases was White's great object, and he lived to prove by his practical success the soundness of his revolutionary theories. In the course of an analysis of the teaching of Semmelweis, comparing it with that of White, Prof. Adami is very severe upon the late Sir William Sinclair, that great Manchester obstetrician who, in eulogising Semmelweis, appears not to have made himself familiar with any of White's admirable researches. Certainly Sinclair could not have ignored the founder of St. Mary's Hospital, Manchester, if he had had any idea of his work, and lest others should pass White over in a similar way Prof. Adami has added to his lecture in its published form six chapters written by White upon Puerperal Fever.

These chapters appeared in a book which was published in London in 1773, and comprise about 100 pages, with the appendix to the second edition which was immediately called for. The book was entitled "A Treatise on the Management of Pregnant and Lying-in Women," and had a voluminous sub-title, in accordance with the style of the eighteenth century, which commences thus, "The Means of Curing but more especially of Preventing the Principal Disorders to which they are Liable," and continues, "With some New Directions concerning the Delivery of the Child and Placenta in Natural Births." White's writings, and the illustrative cases which he quotes, bear out the whole of Prof. Adami's claim for him, and it is an interesting fact that the famous treatise was published almost immediately in America, and translated into German.

Charles White was in his life-time as famous in general medicine and operative surgery as in midwifery. He was the first to excise the head of the humerus, he adopted the sponge as an application in hæmorrhage, and he wrote some observations on gangrene which obtained the fame of Continental translation. He was an especial hero to the founder of the Lloyd Roberts Lectureship, so that no better subject for the inaugural discourse could have been selected.

SIMPLE TRACHEO-BRONCHIAL ADENOPATHY.

IN a recent Paris thesis, Dr. Henri Forgeron[1] remarks that though non-tuberculous enlargement of the tracheo-bronchial glands is well known to pædiatrists, little attention has been paid to it in works of general medicine. He has, therefore, chosen this subject for his inaugural thesis, especially as no monograph has been published on this theme since the introduction of Pirquet's cuti-reaction in 1907. The thesis is based on the study of 19 autopsies on children who had died of various non-tuberculous diseases of the respiratory system, more or less considerable enlargement of the tracheo-bronchial glands being found in each case. Dr. Forgeron points out that though the enlarged glands may reach a sufficient size to compress the neighbouring organs, their action is chiefly one of irritation, and that the principal factor in this action is the accompanying periadenitis. Uncomplicated whooping-cough may occasionally give rise to tracheo-bronchial adenopathy. In such cases the interbronchial glands are the first affected, and the nervous and vascular compression caused by the enlarged glands at the root of the lungs favours the development of broncho-pneumonia. In whooping-cough complicated by broncho-pneumonia, tracheo-bronchial adenopathy is invariably present, the interbronchial and intertracheo-bronchial groups being most affected. Measles is accompanied from the first by tracheo-bronchial adenopathy. The interbronchial glands are liable to be attacked by the pulmonary complications of influenza with special intensity and may become the site of suppuration and be the indirect cause of empyema, especially of the interlobar form. In measles, whooping-cough, and influenza alike the glandular enlargement often outlasts the primary disease, and by weakening the resistance of the bronchi and lungs favour the onset of pulmonary tuberculosis. Typhoid fever affects the tracheo-bronchial glands secondarily to the pulmonary manifestations. As typhoid, like measles, often involves anergy to tuberculin, the nature of the adenopathy cannot be determined with certainty by the cuti-reaction until convalescence. Acute and chronic affections of the upper respiratory tract and pharynx, especially enlarged tonsils and adenoids, are frequently associated with tracheo-bronchial adenopathy. Contrary to the prevalent opinion, the infection does not reach the mediastinal glands by the cervical lymphatic glands, but by descending bronchial infection. Both anatomical investigations and experiments on animals show that there is no connexion between the two lymphatic systems. The direct cause of simple tracheo-bronchial adenopathy is therefore invariably an infection of the lower respiratory tract. The non-tuberculous infection may rouse into activity a dormant tuberculous process and give rise to an acute glandular tuberculosis or generalised miliary tuberculosis.

THE MEDICAL STUDENT OF CENTRAL EUROPE.

WE reviewed recently a pamphlet by Mr. C. P. Blacker [1] which set out the personal experiences of himself and a group of undergraduate companions in the course of a visit to Austria, Hungary, Czecho-Slovakia, Poland, and Germany, the idea being that young Oxford should see for themselves the conditions of student life now prevailing over most of Central Europe as a result of the war. We have since received the following note from a Berlin student which provides confirmation of the letter published this week from our Berlin Correspondent. The student writes in terms which we render quite literally :—

> "It is just the position of the medicals that is the unhappiest imaginable, and posterity has especially to suffer under it. After 10 terms' study, which is now to be extended to 12 terms, some few students succeed in obtaining a post as 'Praktikant' [unqualified assistant], in which, under the most favourable circumstances, they earn at present 200 to 500 marks a month, and receive free board and lodging. A number of Praktikanten do their work simply in exchange for a free midday meal, but a Praktikant may only retain his post for four months, because then a place must be found for other students. To set up in practice on their own is only possible for the richest medicals. Before the war, to provide himself with the most essential instruments, the sum of 2500 marks was needed by a medical, and for this sum one obtained a gynæcological table, an obstetric outfit, a small case of surgical instruments, a steriliser, otoscope and ophthalmoscope, and with this outfit it was possible to get along. Now the same instruments cost about 3,000,000 marks. A voluntary assistant in a clinic was offered last month, along with free board and lodging, a monthly salary of 6000 marks. A number of Berlin practitioners earn their living by serving as waiters in the evenings or as salesmen. A practitioner, an M.D. 29 years of age, is trying at this moment to obtain the position of apprentice in a Berlin business house. In banks, too, you meet with many doctors. It is a fact that in Magdeburg six doctors are in receipt of poor relief."

Our Berlin Correspondent sets out the position in terms of marks, but it can be easily understood that when the "unit" fluctuates between nothing at all and little more than nothing, no deductions can be made from the figures which will allow us to estimate with any certainty what the financial position of medical men and students in Central Europe may be at the present moment. All that we know is that life is excessively difficult for them, and as far as Germany is concerned this has been confirmed by the circular letter to the press from the Universities Committee.

THE TROPICAL DISEASES LIBRARY, LONDON.

THE first annual report of the Tropical Diseases Library, 23, Endsleigh-gardens, N.W. 1, covering the period from its foundation in February, 1921, to July 31st, 1922, has now been issued under the auspices of the Seamen's Hospital Society. The library was formed by an amalgamation of the library of the London School of Tropical Medicine with the collection of bound periodicals belonging to the Tropical Diseases Bureau. The latter are deposited on permanent loan, and in future new volumes will be transferred to the library as soon as they are bound. The report states that at the time of the amalgamation the school library contained 2825 bound volumes (monographs, reports, journals, and transactions of societies), and 2850 unbound pamphlets and reports. At present the reorganised library contains 1292 books (including the most important recent works on tropical medicine, hygiene, and parasitology, together with standard text-books and a few text-books and works of reference on general medicine) and 3457 volumes of 344 different journals and transactions of societies. A total of 122 periodicals from all over the world is regularly received. At the time of the amalgamation the binding of periodicals in the school library was many years in arrears; with the assistance of a grant of £200 made by the school committee for this purpose and for the purchase of modern text-books, 435 volumes have recently been bound. Reprints in the form of pamphlets in the possession of the library now number 2635. The reports of medical and sanitary departments of most of the British tropical colonies and possessions, and a few foreign ones, are regularly presented; there are now 173 bound volumes of these reports. Since its foundation the library has been fortunate in the matter of donations; for instance, the late Sir Patrick Manson presented numerous books and pamphlets, together with the original letters addressed to him by Sir Ronald Ross during the latter's researches on the transmission of malaria in India in 1897–98. A manuscript card-catalogue of the library is now in process of preparation. A subscription to Lewis's Library for five volumes at a time has been opened, and new books are borrowed for the use of students until the library buys copies of its own. The use made of the library has considerably increased since the amalgamation, particularly after the hours of opening were altered to 9 A.M. to 6.30 P.M. Two lists are included in the report—one of 31 volumes missing according to an old catalogue of the School of Tropical Medicine Library, the other of more than a dozen of the most important lacunæ in sets of periodicals, many of which are, of course, out of print and extremely difficult to obtain.

Sir Alfred Yarrow has given to the Royal Society a sum of £100,000, to be used at the discretion of the Council of the Society in promoting scientific research. The noble gift is an expression of his view that the prosperity of this country has been greatly hampered in the past for the want of the promotion of scientific investigation and its application to practical affairs.

WE have been notified that a change of some importance in regard to the examination for the Membership of the Royal College of Physicians in respect of candidates over the age of 40 years has been resolved. It has been the custom hitherto for the President and Censors to grant exemption from the examination in languages and in pathology to candidates over the age of 40 years, but it has now been decided that on and after October next, exemptions shall not be granted solely on the ground of age.

UNDER the auspices of the University of London, a course of three lectures on Recent Work on Inborn Errors of Metabolism will be given at the house of the Royal Society of Medicine, 1, Wimpole-street, London, W. 1, by Sir Archibald Garrod, F.R.S., at 5.30 P.M., on Feb. 28th, March 7th and 14th. At the first lecture, which will take the form of a general review, the chair will be taken by Mr. H. J. Waring, Vice-Chancellor of the University. On the same dates, at 5 P.M., a course of three public lectures on the Cultivation of Tissues in Vitro will be delivered by Mr. A. H. Drew, D.Sc., in the Physiology Theatre of University College, Gower-street, W.C.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

VIII.

THE TREATMENT OF VAGINAL DISCHARGE.

Before considering the treatment of vaginal discharge it is necessary, first, to recognise that the disease is not always worth treating. Occasionally, especially in the unmarried, though considerable complaint may be made, it is found that the amount of discharge is very slight, consists of clear mucus, and is only related to the menstrual period. In these trivial cases it should be pointed out that the ordinary treatment is (*a*) usually futile, and (*b*) of more trouble and inconvenience than the disease. The second point to recognise is that many cases of leucorrhœa are incurable by any means short of an operation, such as high amputation of the cervix, or even hysterectomy, and that these patients must resign themselves to a certain minimum amount of mucus which will remain in spite of any palliative methods adopted.

In all cases the treatment must be adapted to the clinical type of the disease, of which the following are distinctive.

Vaginal Discharge in Little Girls.

The difficult cases of vulvo-vaginitis in children are those in which worms, lice, pruritus and scratching, foreign bodies, and irritating urine can be excluded. Where this is possible, a bacteriological examination of the pus obtained from just inside the hymen by means of a platinum loop should be made, if necessary on more than one occasion, in order to prove the presence or absence of gonococci. Gonococcal or "idiopathic" vulvo-vaginitis is resistant unless properly treated. The vulva should be thoroughly exposed by wide separation of the child's thighs, and gently swabbed twice daily with a 10 per cent. solution of protargol. Should the discharge and soreness of the vulva not clear up after a few days' treatment, a small pledget of cotton-wool about the size of a pea is soaked in protargol and carefully introduced into the vagina by the aid of forceps. As the infection is said not to affect the upper part of the vagina in children, it should only be passed just through the hymen. If the wool pledget is small enough this treatment need not cause pain, but frequently it is only carried out with the greatest difficulty owing to the resistance and screaming of the child. Unfortunately, it is usually necessary. It is well to give a mixture containing potassium citrate, and a few grains of bromide. The child must be restrained from scratching during the night.

Vaginal Discharge in Young Virgins.

This is rarely more than clear mucus due to a functional hyperactivity of the cervical mucous glands, and chiefly evident just before or after the menstrual period. It is also occasionally a concomitant of depressed conditions of general health, fatigue, or anxiety. This form of leucorrhœa should not be treated by local measures, partly because its cause lies rather in general disturbances than local disease; and partly because, for obvious reasons, it is inadvisable to direct the attention of these patients to their genital organs. The rational line of treatment should aim at restoring the general health by suitable means proper to the individual patient. It is well, also, to reassure her that a simple mucoid discharge is of no real importance. If the discharge does not quickly disappear, or cease to cause trouble, a careful inquiry should be made again as to the character of the discharge, and, if necessary, a pelvic examination and bacteriological examination should be carried out. The fact that the patient is regarded as a "young virgin" does not necessarily exclude the possibility of gonorrhœa (as in young children), and, further, a purulent discharge in girls after the age of puberty may be a symptom of tuberculous infection of the pelvic organs.

Purulent, or Muco-purulent Discharge in Nulliparous Non-Virgins.

Though the majority of these patients are suffering from chronic gonorrhœa, it is wise to advise domestic treatment by douches and pessaries, as detailed below, before making a clinical examination. The discharge may disappear under such simple treatment, but such a rapid and easy cure is unusual, and cannot be expected if the gonococcus is present. It is necessary, therefore, after a fortnight of unavailing treatment at home, to insist on making a pelvic examination, and even if there is no bacteriological evidence, and the supporting clinical evidence is meagre or doubtful, it is well to treat the case with the thoroughness demanded by an obvious case of gonorrhœa (care must be taken to exclude the rarer condition of tuberculosis of the pelvic organs). In the absence of intrapelvic lesions, the parts to be attacked are the cervix, the urethra, and Bartholin's glands, if they are tender or palpable.

The cervical canal is the most resistant and difficult to treat. In my opinion it is advisable to commence the treatment of all chronic cases by what amounts to an operation. The patient is anæsthetised, and the urethra is dilated by metal dilators to the size of No. 9 or 10 Hegar. While the orifice is being distended by the largest dilator, a scalpel is taken and the small crypts immediately behind and to one side of the orifice, which so often exude pus on pressure, are opened up by cutting down on to the dilator as it is held in situ. The laid-open crypt is then cauterised by Paquelin's cautery, or, in default of this, by the silver-nitrate stick. The dilator is then removed and several swabs of gauze soaked with 15 per cent. protargol are passed into the dilated urethra, one after the other. The last is left there during the remainder of the operation. The cervix is then exposed, and any erosion is either thoroughly burnt by the actual cautery, or else excised. The cervical canal is then dilated (not the internal os) and its mucous membrane is treated by swabs soaked in 10 per cent. formalin. This is the most penetrating antiseptic we possess, and is better calculated to penetrate into the deep branched glands of the cervix than any other. Moreover, it is a very potent germicide in the strength of 10 per cent. At least five minutes should be spent in the repeated swabbing of the canal with formalin, care being taken that it does not spill into the unprotected vagina. If there is reason to suspect that the body of the uterus is infected on account of menorrhagia and congestive dysmenorrhœa, I dilate the internal os, curette, and introduce an 8-inch-long rubber tube, which is stitched to the cervix by catgut, and strapped to the thigh, through which Milton's fluid or eusol is injected every four hours for the next five or six days, or so long as the tube remains attached to the cervix. After the cervix has been treated, the Bartholin's glands are carefully felt for. If palpable as small, hard bodies, the size of a pea, or larger, they are pinched up by the left finger and thumb and excised by cutting down on to them.

The after-treatment consists in the daily insertion of a protargol bougie (15 per cent.) (1¼ in. × ¼ in.) into the urethra for one or two weeks, and the nightly use of a protargol pessary of the same strength. During this time the patient should use a douche of Condy's fluid. Under this treatment the discharge will frequently clear up entirely, but if it does not, it is due to infection still remaining in the cervix. This may be treated by swabbing the canal thrice a week by an antiseptic, such as 10 per cent. formalin (care being taken to protect the vagina and vulval skin from the fluid) or "violet-green" (1 per cent.) or picric acid (saturated solution in alcohol). It is a tedious method, requires sometimes many weeks, and often fails.

A method which promises better results is the ionisation of the cervical canal by a zinc electrode passed through the external os, while the vault of the vagina contains a dilute solution of zinc sulphate. The current will effect the penetration of the ions for two or three millimetres—i.e., into the mucous glands of the cervix, wherein lurk the gonococci.

Purulent or Muco-purulent Discharge in Parous Women Associated with Lacerations of the Cervix.

If the laceration is slight it may be enough to treat the cervical canal by swabbing it three times a week with some suitable antiseptic, such as formalin, violet-green (1 per cent.), and the nightly use of a protargol pessary (15 per cent.) for two or three weeks, combined with an astringent douche twice a day. Most of these patients will react to some extent to this régime, but a recurrence of discharge on discontinuing the treatment is only too common. In case of failure, it is worth while using the cautery or treating the canal by ionisation. If, however, the laceration is deep, or bilateral, with chronic fibrosis and eversion of the lips of the cervix, the only method to ensure a cure is either the restoration of the cervical canal by the operation of trachelorrhaphy, or even amputation of the cervix. The latter operation is to be preferred in most cases owing to the chronic inflammatory process which has affected the whole substance of the cervix. There is no danger of the plastic sutures breaking down and allowing the former ectropion to recur, a cure can be guaranteed, and any further danger of more serious cervical disease can no longer threaten.

In all cases where there is a gross deformity of the cervix with exposure of the mucosa of the canal, palliative measures are likely to fail, and it is wise to represent to the patient that the discharge is only a symptom of a potentially serious disease which requires radical measures.

Purulent Discharge in Women Past the Menopause.

In the absence of carcinoma of the cervix or body, leucorrhœa in elderly women is likely to be due to a pyogenic vaginitis or endometritis. Sometimes this has been set up by the wearing of a pessary, but in others there is no obvious cause. Diagnosis is made by inspecting the vagina and cervix through a speculum. The mucous membrane, especially in the upper part, is dotted with bright-red maculæ, which are liable to ooze blood on gauze pressure. If pus can be seen exuding through the external os, it is certain that a purulent endometritis coexists, but if nothing is seen a negative diagnosis of corporeal infection cannot be inferred.

The treatment is the insertion of a protargol pessary (15 per cent.) each night for about a fortnight, and a douche of alum solution thrice daily during this period. Under this treatment a simple vaginitis will rapidly clear up, without any tendency to recur, but should it have little or no effect on the discharge it must be inferred that there is an infection of the body of the uterus, with possibly pus locked up therein (pyometra). An intermittent purulent discharge after treatment has been carried out also points to the condition of pyometra.

If, therefore, a discharge persists after treatment for a fortnight, it is proper to dilate the cervix, swab out the cavity of the uterus, and fix therein an irrigation tube as described above. Failure to provide drainage and irrigation will almost certainly lead to the recrudescence of the infection and discharge. The cavity of the senile uterus readily responds to drainage and irrigation, and it is usual for the disease to be cured finally by treatment on these lines for a week.

THE REGISTRAR-GENERAL'S STATISTICAL REVIEW.

ATTENTION has already been drawn to the convenient resumption of royal octavo in lieu of folio foolscap in the first section of the Registrar-General's Annual Report for 1921. The change is pleasant, as the former volume was doubtless bulky and difficult of handling. Whether the change will have been purchased too dearly can only be finally determined when the three parts, of which the volume now under review is the second, have all appeared. Meanwhile we must note regretfully a number of definite losses for the increasing public who study our national life records.

The present volume is handy in form and comparatively light, but this result has been produced at the expense of inconveniently narrow margins of pages, and in the more important tables at the expense of a type which is small and crowded, and which will be a severe trial to many eyes. Comparison of the old and the new tables reveals that there have been omissions and compressions, which may reduce the permanent value of the report. To this point we may need subsequently to return.

The Omission of Yearly Birth-rates.

The 83 annual reports of the Registrar-General which preceded this volume comprised the most complete statistics extant of the vital conditions of any community, displaying decade by decade in steadily increasing fullness and completeness the course of fatal disease in this country and in its constituent parts. Are we now starting on a career of restricted reporting, in which information is to be severely supervised from the point of view of its utility or necessity; forgetting that this report is a mine in which others may dig and find riches, as well as the staff of the General Register Office, and not a factory in which finished products are prepared for the edification of the public? We shall judge better when the three sections of the "Review" are before us. Meanwhile the most unfortunate omission from the present volume is that of birth-rates for the entire country for a series of years. We are not reconciled by the announcement that a further volume of the "Review" is to appear—viz., Part II.—which will contain "Civil" statistics, as distinguished from the "Medical" statistics in Part I., the volume now under consideration. The search in another volume for statistics in which births are concerned will be inconvenient and cause unnecessary labour for many medical workers in statistics. We note that in the present volume actual births for different areas are given; and there the interest of the medical worker is assumed to cease. To be consistent these births should have been omitted from the present volume; to be useful birth-rates for the chief areas should have been given. The entire conception of division of vital statistics into "medical" and "civil" appears to us to be based on some misapprehension of public needs. Many thousands of civilians rightly take deep interest in medical statistics; and medical statisticians are even more closely concerned with the collateral statistics of marriages and births, without which statistics of deaths lose much of their utility, whether for purposes of administration or research.

The Comments on the Tables.

If the separation of part of the birth statistics from the statistics of death is unfortunate, still more so is the publication of the present volume (Part I., Medical) divorced from the text illustrating and commenting on its tables. In past reports this text drew attention to the points of salient interest, and comprised also those invaluable studies of special statistical problems with which each Annual Report of the Registrar-General has been enriched, and never more so than in the last 10 or 15 years. This text is to appear at a later stage, in a separate volume—a further complexity; and it is claimed that the new method aids expedition in publication, as comments on the tables necessarily must be made after the tables are completed. The present volume is issued nearly 14 months after the year with which it is concerned, an interval which does not imply expedition in publication.

Expedition of publication is rendered the more necessary, because the present volume of the "Review" comprises the statistics of infectious diseases in each administrative area of England and Wales, which for the last dozen years have been published by the Local Government Board and by the Ministry of Health not later than April of the year following that with which they were concerned. These statistics have permanent value which is not affected by delay in issue; but they have important immediate utility for medical officers of health, and this is almost destroyed by the now delayed publication.

The changes thus instituted raise the general question as to how far it is permissible unnecessarily to change the character and contents of important statistical tables which have been standardised and perfected by the experience of many years. Some changes are necessary. In the present volume some such changes are made to adapt the list of causes of death to the new International Rules. But here the changes are specified, and warning (perhaps inadequate) of risks from changes in classification is given. But apart from essential changes, alterations of standard tables, or even of their order, and contractions of fuller information previously given are to be deprecated, as rendering the stony and difficult path of the statistician unnecessarily arduous.

Excessive Price of the Report.

And this brings us to our last point. The annual reports of the Registrar-General are a national possession to be jealously guarded, and one to be made as accessible to the general (including the medical) public as is practicable. Can this object be met when the present volume is marked "price 15*s.* net"? This excessive price is given as a reason for separating the text of the report (not yet published) from the tables; a plan which is exactly comparable to the procedure of a trading company, if it published its report separate from its balance-sheet. Should not some medical Member of Parliament take up this question of price of official publications in the House of Commons? Presumably the price of this present volume is fixed by a process of "costing," to cover outlay on printing and publication. But to be consistent it should include the estimated rental value of the part of Somerset House and of the salaries of that portion of the staff of the General Register Office engaged in the tabulation and preparation of this report. If these expenditures are to be given to the public without direct payment, why exact complete payment for the printing of the report? To do so defeats the object of the compilation, in which large numbers are interested, who are now precluded from its study owing to the large price charged for it.

MEDICINE AND THE LAW.

IN THE MATTER OF DEATH CERTIFICATES.

A LETTER from Dr. W. Allingham in our present issue and another from Dr. H. A. Burridge, published in THE LANCET of Feb. 10th, call attention to the attitude of Dr. R. L. Guthrie, coroner for Poplar, when he criticised unfavourably the conduct of the house surgeon of Poplar Hospital, in connexion with the death of a woman aged 50, upon whose body he was holding an inquest. The woman, apparently on her way to the hospital, which she had before visited as an out-patient, to get a "bottle of medicine," was taken ill in an omnibus, reached the hospital, and was put to bed, dying half an hour later. The house surgeon, in order to test the accuracy of his diagnosis of a natural death, obtained the permission of the relatives to make an autopsy, and having done so, sent some of the internal organs for analysis, as indications of poisoning were present. The coroner questioned whether in the circumstances the medical man had "attended the deceased in her last illness," so as to entitle him to certify the cause of death, and held that his proper course would have been to communicate with the coroner at once. To state the law precisely upon such occasions and to apply it to the circumstances of a particular case in the matter of death certification and inquests is not always easy. Acts of Parliament have been framed with a view to the universal accurate recording of deaths and their causes and the detection of crime in the public interest, but as the law stands the attaining of this desirable object smoothly and with certainty is not possible without some degree of voluntary coöperation between the medical profession, coroners, and the public itself. That appears to us to be the situation.

There is no legal obligation upon a doctor to communicate in the first instance with the coroner. By the Coroners Act of 1887, however, the coroner is bound to hold an inquest where he is informed that a dead body is lying within his jurisdiction and there is reasonable cause to suspect that such a person has died either a violent or an unnatural death or has died a sudden death, of which the cause is unknown. On the other hand, under the Act of 1874, which governs the registration of deaths, a certificate of the cause of death of a person who has been attended "during his last illness" by a medical practitioner is to be given by him stating the cause of death "to the best of his knowledge and belief." As to what constitutes "attendance during the last illness" of a dead person, this appears to us to be a question of fact, such as any jury has to determine, when the law has been explained by the judge trying a case. Juries do not always agree and the law itself might conceivably be made more definite, but it should be noted that the words used are "during his last illness" and not merely "immediately before death" or any such phrase. It may well be possible to state the actual or immediate cause of death when a person has been brought under a doctor's observation in a moribund condition, but this does not necessarily eliminate all reason for the coroner's intervention. A child, for example, may be brought into a hospital in a dying condition by persons who have had every reason not to prevent its death. In the case at Poplar the house surgeon, in the first instance, may have justifiably formed an opinion as to the cause of his patient's death, and he may have had the right with the relative's consent to verify his opinion. When, however, the possibility of poisoning presented itself to his mind he would have been well within his rights in refusing a certificate and leaving the coroner to be informed by the relatives via the registrar—such refusal being based either on the ground that he had not attended the patient during his last illness, or because he believed that the death was in other aspects one for the coroner's consideration.

There remains the alternative of coöperation, well brought out in the evidence given before the Departmental Committee on Coroners (1909), when the late Dr. G. Bateman, called as general secretary of the Medical Defence Union, was questioned by Sir William Willcox, a member of the Committee.

Question: "In a considerable number of cases where the death is not certified and the coroner investigates the case and comes to the conclusion that no inquest is necessary, does not the medical practitioner give a certificate after the coroner has investigated the case?"

Answer: "Yes, the coroner would tell the medical man that he is justified in giving a certificate; in certain instances the medical man is doubtful about it and refers the matter to the coroner, who hears his statement or reads his written statement, and tells him he can certify, and he does so." The evidence before the Departmental Committee touches at other points upon the subject of certification, but their report does not appear to recommend any alteration of the law which might have prevented the misunderstanding at Poplar. When the revision of the Act of 1887 takes place these points must be considered by Parliament. Meanwhile, some of them might usefully be discussed by the Medico-Legal Society, for medicine and the law are alike interested.

LUNACY IN EGYPT.

THE report [1] for 1921 of the Lunacy Division of the Ministry of the Interior, Egypt, gives full information, not only as to lunacy administration in that country, but as to the steps by which its present efficiency has been attained. The service has been in existence for 28 years, and during that comparatively short period has advanced to a position which in many respects is remarkable.

The Two Asylums.

Recent building extensions at the two asylums at Abbasîya and Khanka have increased the total number of available beds to 1841, and the actual number of patients in residence has been as high as 2364. The numbers of the staff have risen from 73 in 1895 to 588, and the annual expenditure on the service has increased twenty-fold. With each increase in the scale of treatment there has been an advance in method, amounting over the whole period to the substitution of therapeutics for mere restraint. The newest buildings are constructed on the villa system, and large numbers of the patients are usefully employed on farms. Mechanical restraint is practically never employed, and seclusion little; the number of doses of hypnotics given amounts only to three per patient per annum, and suicides and accidents are rare. There are indications in the report that the work of the attendants is well carried out. It appears that the insane Egyptian is peculiarly responsive to considerate treatment, and that the post of attendant is much sought after, even to the extent of producing 200 applications for five vacancies. These two circumstances, and the fact that ill-treatment of a patient is followed by instant dismissal with no possibility of reinstatement, have evidently combined to raise the work of the attendants to a high standard. Facilities exist for pathological work, since references are made to the Wassermann and gold-sol tests, and to the bacteriological investigation of dysentery cases, but it does not appear whether the laboratory employed is in either of the asylums, or whether, on the other hand, such specimens are sent elsewhere. As far as a report, however full, can give a true picture of life in such an institution, it is evident that the Egyptian asylums are well abreast of the times.

Types of Mental Disease.

Other circumstances connected with them result from the totally different conditions prevailing in that country as compared with those in England. A large proportion of the patients are either criminals or vagrants, and the recent increase in the admission-rate is explained by the greater activity of the police in dealing with the latter, particularly in remote districts. Owing to the exorbitant demands thus made on the existing accommodation, the average duration of treatment is only two years, and patients are frequently discharged before recovery. For this reason the recovery-rate is valueless for comparison with that of an English institution. Not only is it so for this reason, but because the types of insanity are different. The list is headed by pellagra, which accounts for one-fifth of the total admissions. This disease occurs in country districts, whereas the incidence of almost every other form is much higher in the towns. Recovery from pellagrous insanity appears to be exceptional, and experience in Egypt has thrown no important light on its ætiology, although it is stated that "cases of pellagrous manifestations are frequently seen which cannot be explained by a deficiency in quality or quantity of food." The incidence of general paralysis is much lower than in England, but its distribution among the different races is of interest in that it appears to contradict the assumption that this disease is produced by a special "neurotropic" form of syphilis. The suggestion has been made that Egyptian syphilis is less liable to be followed by general paralysis than that of other countries, since the latter disease is rare among Egyptians. But of the Maltese in Egypt, who are subject to the same variety of syphilis, no less than 18 per 1000 develop general paralysis, and of the insane Maltese treated 20 per cent. were general paralytics, as against 5 per cent. of general paralytics among the total admissions of all races. These statistics are naturally inconclusive without parallel figures as to the incidence of syphilis itself in the two races, but the strong suggestion is that other factors are concerned. The effect of such influences as addiction to alcohol or hashish, and urban as distinct from rural habits of life, is clearly shown in the statistics of other forms of insanity.

The general incidence of insanity shows a remarkable seasonal variation, rising rapidly during the excessive dry heat of early summer; the curve representing this variation corresponds closely to that of the murder-rate, which in Egypt is exceptionally high.

Legislative and Political Aspects.

At the end of this report there is printed a draft of the proposed new Lunacy Law for Egypt. Apart from variations necessitated by a different judicial system, the provisions appear almost identical with those of the English laws. It can be inferred from other parts of the report that the majority of the patients are such as would be classed in this country as paupers, and that in any case they are detained on a single certificate. Nearly 10 per cent. of these during the year under review were invalid; in some cases even the name, date, or signature were omitted. Now, however, that public confidence in asylum treatment is becoming general in Egypt, it can be presumed that a number of better-class patients will be certified on the petition of their relatives, whereas this action appears at present to be taken chiefly at the instance of the police.

This report derives particular interest from the fact that it coincides with a change in the political status of Egypt. It is believed that under the new government the British element in the public services is being eliminated. This, therefore, is a record of the degree of achievement in lunacy administration which was attained under British control, and it can be said without hesitation that the achievement is a considerable one, perhaps unparalleled in any similar State. Dr. John Warnock, to whose direction these important changes are largely due, remains superintendent of Abbasîya, the larger of the two asylums, and chief medical officer of the service.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Financial Distress in Berlin Hospitals.

THE numerous private hospitals of Berlin, of which the majority belong to religious communities, have petitioned the municipal authorities for financial support, without which they will be compelled to close altogether. The St. Hedwig's (Roman Catholic) Hospital enjoys a special reputation among the public for good nursing and good food; a Jewish hospital, opened in 1913, has already been compelled to close its obstetrical ward for lack of means. Large

---

[1] Government Press, Cairo. Price P.T.10.

Lutheran establishments are the Bethania, Lazarus, and Elisabeth Hospitals. The public hospitals are either State or municipal institutions. The Charité Hospital, the oldest in Berlin, in which are the majority of the university clinics, belongs to the State. Of the municipal hospitals the largest is the Virchow Hospital, containing about 3000 beds, and opened a few years before the war; this institution, built on the pavilion system, is the size of a small town, containing a square in front of the operation building, a church, and a large administrative block. Among other municipal establishments may be mentioned the Friedrichshain Hospital, opened in 1874, which was the first institution built with separate pavilions; it was designed by the late Prof. Virchow, then a municipal councillor. All these, and the other municipal hospitals, suffer from chronic over-pressure; the number of beds has not been increased since the war, for lack of means, but the population has enormously increased—partly because all the Berlin suburbs, which formerly had administrations of their own, have been amalgamated with the city. As some of these suburbs had no adequate hospital accommodation, their inhabitants now have the right of admission to the Berlin hospitals. The closing of private hospitals, or reduction of the number of their beds, would simply mean a further overcrowding of the public hospitals. The city of Berlin is nearly bankrupt, and has no means of building new hospitals or enlarging the existing ones. The chief of the municipal medical department, Dr. Rabnow, lately stated that each new bed would mean an expense of a million marks. In September, 1922, the municipal hospitals had a deficit of 10 million marks a day, produced by the enormous rise of all expenses—heating, salaries, food, &c. The expenses of private hospitals have risen equally, and it has been moved in the municipal parliament that the request of the private hospitals for support should be granted.

German Hospital System.

The hospital system in this country differs radically from the English system. In Germany free admission is very rare; a patient who requires hospital treatment must procure a ticket of admission either from his sick-club (the majority of patients nowadays are club members) or, if poor, but not a club member, from a poor-law medical officer, or must pay a month's fees in advance. Urgent cases—accidents and contagious diseases—are, of course, admitted without any formality, but after admission inquiries are set afoot as to which club or which poor-law authority is liable to pay the expenses, or whether the patient is able to pay himself. The hospital administrations are, of course, generally very lenient in enforcing payment; a patient is never dismissed early because he cannot pay. The hospital charges in the general wards were 5 marks a day before the war, but are now 800 marks a day, including medical attendance and operation if necessary. The sums charged are not in the least sufficient to cover the actual expenses of the hospital; in public hospitals the deficit is covered either by the State or the city, and in private hospitals by the religious community or private corporation to which the hospital belongs. The low hospital charges in that way mean a gift to the sick-clubs or to private individuals admitted to the general wards. Private hospitals have single rooms for better-class patients, who are expected to pay for treatment, operations, and dressing materials in addition to their keep.

In Germany all the physicians and surgeons of the public hospitals are State or municipal officials who have to devote a large part of their time to hospital work. Their number is much smaller than in England; excepting the largest hospitals, there is usually only one chief physician and one chief surgeon for each hospital. They are aided by a number of assistants who reside in the hospital and do the routine work; they are in turn assisted by sub-assistants, young medical men in their "practical year"[1] and by students acting as dressers or clinical clerks. The salaries of these posts were rather small even before the war, but the appointments were much sought after, as hospital work offers good opportunities of thorough training, and enhances the reputations of medical men in the eyes of the public. Before the war an assistant received 250 marks a month with free board and residence; but now the figure is 100,000 marks a month with board and residence. Other students obtain, quite frequently, occupation in commercial houses. The chief physicians and surgeons received before the war 8000 marks and free residence for themselves and their families; they now receive about 300,000 marks a month. In private hospitals the remuneration is smaller, varying much in different hospitals.

Conscientious Objection to Vaccination.

The conscientious objector to vaccination has hitherto been almost unknown in this country. There were, of course, a number of more or less conscientious objectors, but they had no legal recognition, and the district medical officers could summon them before police courts and issue warrants for compulsory vaccination of children. Some time ago Prof. Grotjahn, a socialist member of the Reichstag, and professor of social hygiene at the University of Berlin, suggested in Parliament that the vaccination law should be amended and a conscience clause inserted. In an article in the *Deutsche Medicinische Wochenschrift* he admitted that small-pox rapidly decreased in the army when compulsory vaccination was introduced in 1834, whilst it continued to be epidemic in the civil population, among whom vaccination became compulsory only in 1874. Prof. Grotjahn is of opinion that vaccination alone is not responsible for the decline of small-pox, but that better hygiene and isolation of cases play their part, but he does not deny the influence of vaccination. Since other countries, employing measures less rigorous than those in force in Germany, show a similar decrease we must, according to him, revise our opinion as to the absolute value of compulsory vaccination. He insists that in England, notwithstanding the existing provision in favour of the conscientious objector, the incidence of small-pox is nearly the same as in Germany, and believes that Germany might also introduce the same provision without fear of an outbreak. By that measure, in his opinion, vaccination would probably become more popular than under the present system. His views were energetically opposed by Dr. Prinzing of Ulm, a well-known medical statistician, who showed that the mortality from small-pox has decreased everywhere, but not to the same degree as in Germany. He stated that during the war the German army in Poland lived among a population where small-pox was epidemic, and where hygienic conditions were very unsatisfactory, yet very few cases of small-pox occurred among the troops. With her long Polish frontier, Germany is not protected against the introduction of contagious diseases as England is protected by the sea. In her present financial condition Germany does not possess the means for establishment of a sufficient number of the isolation barracks whose construction was suggested by Prof. Grotjahn. Dr. Gins, chief physician of the small-pox department of the Robert Koch Institute, is also a strong advocate of compulsory vaccination. He stated that 95 per cent. of deaths from small-pox were of people above 40 years of age, whilst before the introduction of compulsory vaccination 90 per cent. of the deaths were those of children under 10 years of age. This change could, he said, only be explained by active immunisation of the whole population. Germany will probably continue to employ compulsory vaccination, although some of the existing forcible police measures may be abandoned in favour of more lenient methods.

Feb. 14th.

ROYAL COLLEGE OF SURGEONS OF ENGLAND: HUNTERIAN FESTIVAL.

MR. RUDYARD KIPLING'S ADDRESS.

A dinner was held in the library of the College, Lincoln's Inn Fields, on Wednesday, Feb. 14th, in celebration of John Hunter's anniversary, when a large number of the Council were present to meet a distinguished group of guests, who were received by Sir Anthony Bowlby, the President, and Sir D'Arcy Power and Sir Berkeley Moynihan, the Vice-Presidents.

The toast list was short and the speaking was very good. After the usual loyal toasts, the Memory of John Hunter was received in silence, when the President proposed the health of the Visitors, making detailed allusion to many of the guests of the College. He paid a special tribute to the work of the Lord Chancellor, Lord Cave, who as chairman of the Committee on the Voluntary Hospitals had given what might be described as a second charter to the voluntary hospital system of the country. In his reply the Lord Chancellor referred with admiration and gratitude to medical men and laymen alike, who amid great and diverse difficulties and discouragements supported the voluntary system. He entered, he said, upon his duties as chairman of the Hospitals Committee with an open mind, and he had become convinced that the English system was far superior to that prevailing under the system of State hospitals met with abroad. The evidence which had been given before him compelled him to say with a grateful heart that the genius of the English-speaking race had evolved a system which was responsible for the continued health and happiness of many millions of our fellow countrymen.

Mr. Rudyard Kipling on the Mystery of Man.[1]

Mr. Rudyard Kipling proposed the health of the Hunterian Orator. He said: In the oration to which we have listened this afternoon, Sir John Bland-Sutton touched on that noble verse in Ecclesiasticus: "Honour the Physician with the honour which is due to him for the uses which ye may have of him." There is an alternative reading, which runs, "Honour a Physician before thou hast need of him." It is also seemly to honour him after that event. (Laughter.) And I have not another justification, but an excuse, for speaking in such an assembly as this. I am, by calling, a dealer in words, and words are, of course, the most powerful drug used by mankind. Not only do words infect, ergotise, narcotise, and paralyse, but they enter into and colour the minutest cells of the brain, very much as madder mixed with a stag's food at the Zoo colours the growth of the animal's antlers. Moreover, in the case of the human animal, that acquired tint, or taint, is transmissible.

A Poetical Dream.

There is a legend which has been transmitted to us from the remotest ages. It has entered into many brains and coloured not a few creeds. It is this: Once upon a time, or rather, at the very birth of time, when the Gods were so new that they had no names, and Man was still damp from the clay of the pit whence he had been digged, Man claimed that he, too, was in some sort a deity. The Gods were as just in those days as they are now. They weighed his evidence and decided that Man's claim was good—that he was, in effect, a divinity, and, as such, entitled to be freed from the trammels of mere brute instinct, to enjoy the consequence of his own acts. But the Gods sell everything at a price. Having conceded Man's claim, the legend goes that they came by stealth and stole away this godhead, with intent to hide it where Man should never find it again. But this was none so easy. If they hid it anywhere on Earth, the Gods foresaw that Man, the inveterate hunter—the father, you might say, of all hunters—would leave no stone unturned or wave unplumbed till he had recovered it. If they concealed it among themselves, they feared that Man might in the end batter his way up even to the skies. And, while they were all thus at a stand, the wisest of the Gods, who afterwards became the God Brahm, said, "I know. Give it to me!" And he closed his hand upon the tiny unstable light of Man's stolen godhead, and when that great hand opened again, the light was gone. "All is well," said Brahm. "I have hidden it where Man will never dream of looking for it. I have hidden it inside Man himself." "Yes, but whereabouts inside Man have you hidden it?" all the other Gods asked. "Ah," said Brahm, "that is my secret, and always will be unless and until Man discovers it for himself."

Man as the Hunter of Truth.

Thus, then, gentlemen, does the case stand with Man up to the present. Consider, for a moment, the pathos of the poor brute's position. You all know the common formula for him. "Born of Woman, on Woman designed to beget his life—the natural quarry of the Seven Deadly Sins, but the Altar of an inextinguishable Hope." Or, more scientifically (I regret I am not a scientific person), he might be defined as "An imperfectly denatured animal intermittently subject to the unpredictable reactions of an unlocated spiritual area." (Laughter.)

And it is just this search for this unlocated spiritual area, whether it be a growth or a survival, which has preoccupied Man from that day to this. The priest and the lawgiver have probed and fished for it all through the ages; but, more than any other, through all the ages, the leech, the medicine-man, the healer, has been hottest on its track. He has searched wherever he dared—openly or furtively—in safety or at the risk of his life. In the early days the Astrologer-Physician, as he called himself, dreamed that the secret of Man's eternal unrest was laid up in the sun, moon, and stars; and consequently, since all created things were one in essence, that an universal medicament for Man's eternal woes would be discovered upon earth. So he searched the earth and the heavens for those twin secrets, and sacrificed himself in the search as a matter of course. Later, when the embargoes on the healing art were lifted, when, at last, he was permitted to look openly into the bodies of mankind, the nature of his dreams changed for a while. He had found more wonders beneath his knife than earth or the planets had heretofore shown him. And that was barely ten generations ago. Once again, the surgeon, as he had become, renewed his search, and once again sacrificed himself in the search as his passion drove him. There is no anæsthesia so complete as man's absorption in his own job. (Hear, hear.)

The Old Quest and the New Name.

In the teeth of the outrageous, the absurd disabilities imposed on him, Man, the imperfectly denatured animal, who cannot trust the evidence of his own senses in the simplest matter of fact; whose evidence on the simplest matter is coloured by his own iniquities; Man, always the hunter, went up against the darkness that cloaked him and every act of his being, to find out what order of created being he might be. He called it scientific research. It was the old quest under a new name. But, this time, the seekers who headed it, unlike the priest and the lawyer, admitted that they knew very little. (Laughter.) Experience had taught them to be humble. For that reason their knowledge was increased. They moved forward into areas of the body, which, till then, had denied themselves to Man's hand. They were turned back, without explanation, from other areas which, as yet, would tolerate no spying. They were bewildered by mysteries which, under some new marriage of observation upon accident, or some predestined slip of the knife, resolved into—mysteries profounder still! Is it any wonder that the old dreams came back? The dream of the essential unity of all created things—the dream that some day that which men called life might be led into matter which men called dead—the boldest dream of all, that eventually Man might surprise the ultimate secret of his being where Brahm had hidden it, in the body of Man. And, meanwhile, their days were filled, as yours are filled, with the piteous procession of men and women begging them, as men and women beg of you daily, for leave to be allowed to live a little longer, upon whatever terms.

A Dread Art.

Is it any wonder, gentlemen of the College of Surgeons, that your calling should exact the utmost that man can give—full knowledge, exquisite judgment and skill in the highest, to be put forth, not at any self-chosen moment, but daily at the need of others? More than this. Your dread art demands the instant, impersonal vision which in one breath, one beat of the pulse, can automatically dismiss every preconceived idea and impression, and as automatically recognise, accept, and overcome whatever of new and unsuspected menace may have slid into the light beneath your steadfast hand.

But such virtue is not reached or maintained except by a life's labour, a life's single-minded devotion. Its reward is not only the knowledge of mastery and the gratitude of the layman, which may or may not bring content. Its true reward is the dearly-prized, because unpurchasable, acknowledgment of one's fellow craftsmen.

I have the honour to-night of speaking before you, who are the masters in your craft, and I do not give you the name of the least in your long line of seekers who follow the quest Brahm set them, when I ask you to drink the health of "Sir John Bland-Sutton, a master among masters." (Loud cheers.)

Hunter and Kipling.

Sir John Bland-Sutton, in response, said that his concern was with the human body—the greatest animal in the world was man, because he possessed brains. While he had been studying the body, Mr. Kipling had been studying psychology and the psychology of animals, which was mixed up not only with the religion of Brahm, Buddhism, but with every religion in the world, and the idea of angels, and Balaam and the ass, Jonah and the whale, and Tobias and his dog all arose in some Kiplingish brain. "The Jungle Book" would go down to generations with Beauty and the Beast, Red Riding Hood's wolf, and so forth, because the lessons of Kipling were taught not as day dreams, but as the results of the study of the animals themselves, then treated beautifully, simply, and artistically by a real genius. Men of the stamp of Hunter and Kipling inspired other men. No man attained permanence unless he inspired others to imitate him, and those who, during the life-time of a great teacher, spoke well of him were often mockingly called disciples by contemporaries. But when one of those great men died some of the first to speak well of him were those who had been his detractors. Men very rarely spoke well of their friends in their presence, except in after-dinner speeches, and John Hunter was not appreciated by his contemporaries.

The following were present as guests of the President and Council of the College:—

Sir Hugh P. Allen, Mus.Doc., Sir F. W. Andrewes, Master of the Apothecaries' Society, Mr. Butler Aspinall, K.C., Master of the Barbers Company, Mr. N. G. Bennett, Dr. R. A. Bolam, Judge Ivor Bowen, Right Hon. Lord Justice Banks, Mr. R. H. Burne, Sir F. Morgan Bryant, Viscount Cave (Lord Chancellor), Sir William Church, Master of the Clothworkers' Company, Sir Frank Colyer, Lord Dawson, Rev. W. H. Draper (Master of the Temple), Master of the Drapers Company, Mr. C. H. Fagge, Sir Walter Fletcher (Secretary, Medical Research Council), Lieut.-Colonel F. E. Fremantle, M.P., Sir Archibald Garrod (Professor of Medicine, University of Oxford), Prof. G. E. Gask, Mr. F. Gill (President, Institution of Electric Engineers), Sir Rickman Godlee, Lieut.-General Sir John Goodwin, Dr. W. S. A. Griffith, Master of the Grocers Company, Mr. H. A. Gwynne, Sir W. Hale-White (President, Royal Society of Medicine), Viscount Hambleden, Mr. C. L. Hartwell, A.R.A., Sir Wilmot Herringham, Surgeon Vice-Admiral Sir Robert Hill, Mr. Montagu Hopson, Sir H. Hughes-Stanton, R.A., Sir J. Y. W. MacAlister (Secretary, Royal Society of Medicine), Sir William, Macewen (President, British Medical Association), Major-General Sir William Macpherson, Sir George Makins, Dr. John Mason, Alderman Edward C. Moore (Lord Mayor of London), Master of the Merchant Tailors Company, Air Commodore D. Munro, Sir David Murray, R.A., Mr. John Murray, Mr. P. J. Neate, Mr. H. S. Pendelbury, Mr. L. Bathe Rawling, Sir Humphry Rolleston (President, Royal College of Physicians), Master of the Salters Company, Colonel Stuart Sankey, Mr. S. G. Shattock, Mr. Justice Shearman, Sir C. S. Sherrington (President of the Royal Society), Surgeon-General W. B. Slaughter, Sir Squire Sprigge, His Honour Judge Stanger (Treasurer of Lincoln's Inn), Lord Stanmore, Mr. Sheriff J. E. K. Studd, Mr. A. T. Teniers, Prof. H. Tonks, Sir John Tweedy, Viscount Ullswater, Sir Aston Webb, P.R.A., Mr. E. H. N. Wilde, and Sir Dawson Williams.

The following Members of the Council were present:—

Sir Anthony Bowlby, in the chair, Sir D'Arcy Power, Sir Berkeley Moynihan, Sir Charters Symonds, Sir Charles Ballance, Sir John Bland-Sutton, Mr. H. J. Waring, Mr. W. G. Spencer, Mr. F. F. Burghard, Sir Herbert Waterhouse, Mr. T. H. Openshaw, Mr. Raymond Johnson, Mr. V. Warren-Low, Mr. James Sherren, Mr. E. W. Hey Groves, Sir Cuthbert Wallace, Mr. F. J. Steward, Mr. Thelwall Thomas, and Mr. R. P. Rowlands, with Mr. V. G. Plarr (librarian) and Mr. S. Forrest Cowell (secretary).

MEDICAL WOMEN'S FEDERATION.

MEDICAL WOMEN IN THE POST OFFICE.

THE Council of the Medical Women's Federation have addressed to the Postmaster-General a letter on the question of inequality of salary as between medical men and women. The letter points out that the Federation has as one of its primary objects the organisation of medical women in order that loyalty and a high standard of work may prevail amongst them, and that the principle of equal payment as between medical men and women for equal services rendered might be upheld. The letter goes on:—

The first appointment of a medical woman to a post in the General Post Office was made in 1882, and at that time there was no comparable post on the male side. In 1895 an assistant female medical officer was appointed on the same terms (£200–£300) as male assistant medical officers. This equality of payment for equal services rendered continued to exist until 1911, when an extra post was created on each side, the minimum salary for each being equal, but the maximum for the male officer was increased. A protest was made by the senior female medical officer, and a London candidate withdrew her application. A provincial graduate who was in ignorance of the inequality was appointed. In 1914 she resigned.

During the war only temporary medical officers were appointed, and these at an equal salary of eight guineas per week. In 1920 the question of permanent appointments was again raised, and the senior female medical officer, who again made a strong appeal for the abolition of inequality on sex grounds, was assured by the then chief medical officer that the work of the women medical officers in no way fell short of that of the men. In spite of this statement, in 1921 the salaries of temporary male medical officers were raised to ten guineas while the temporary female medical officers received nine guineas only. A protest was made by the female medical staff. At the present time all the assistant female medical officers in the General Post Office receive a salary on the scale of £250–£400 with bonus, as against the assistant male medical officers' £300–£500 with bonus in proportion.

In view of the inequality which now exists in the salaries of the medical staff of the General Post Office, we desire to lay stress on the fact that medical women receive exactly the same training and pass the same examinations as medical men, and also that they are capable of doing, and actually do, exactly similar work and undertake the same responsibilities as the men. We understand that the record in respect of sickness of medical women in the General Post Office service is good, and that the only retirement so far has been at the ordinary age limit. The medical women have never asked or required any extra favours or special consideration, and have readily worked longer hours whenever the necessity for this has arisen. Inequality of payment will tend to prevent the better qualified and more experienced women from offering themselves for appointment to General Post Office posts.

The letter is signed by the office bearers of the Federation, Lady Barrett, M.D. (President), Miss Frances Ivens and Dr. Mabel Ramsay (Vice-Presidents), Miss L. B. Aldrich-Blake (Hon. Treasurer), and Dr. F. M. Dickinson Berry (Hon. Secretary).

Correspondence.

"Audi alteram partem."

HOSPITAL POLICY.

HOSPITAL SAVINGS ASSOCIATION.

To the Editor of The Lancet.

Sir,—I have just seen in your issue of Feb. 3rd a letter signed by the vice-chairman and senior physician of the West-End Hospital for Nervous Diseases relating to the scheme of the Hospital Savings Association, and while I do not wish to enter into a general discussion on the merits of the scheme, I do wish to clear away misunderstandings.

Will you therefore allow me to state shortly :—

1. The scheme involves no interference whatever with the present independent management of hospitals.

2. It is not an insurance scheme ; it does not set out to bring new classes of patients to the hospitals, but only to enlarge and organise the collection of contributions from the classes who already use the hospitals ; it leaves unimpaired the right of the hospital to decide what cases are suitable for admission to hospital treatment and the order of priority in which applicants, whether contributors or not, are admitted.

3. The only alteration in the present almoning arrangements is that the inquiry as to means by the hospital becomes unnecessary in the case of contributors, because it will have taken place before the contributor applies for hospital treatment. Hospital income limits have been defined, and every contributor who applies for hospital treatment will bring with him an authenticated statement that his income falls within them. In any case of suspicion the hospital will be afforded full opportunity of investigation through the Association.

4. The payment, or non-payment, of medical staffs is a question of hospital management, and in such questions the Association is under a pledge to the hospitals not to interfere.

5. I can see nothing that "controverts the existing principles of the voluntary system" in collecting contributions from wage-earners and using them to help the hospitals which have treated contributors. The one desire of all of us who have taken the lead in this matter is to preserve the voluntary system. The extent of the support which the scheme has already received from hospitals, employers, and representative wage-earners drawn from many trades, confirms me in the confident belief that we shall succeed.

I am, Sir, yours faithfully,

Hambleden,
Chairman, Hospital Savings Association.

EDUCATION IN CANCER PROBLEMS.

To the Editor of The Lancet.

Sir,—Dr. W. H. Woglom, Associate Professor of Cancer Research in Colombia University, New York, disagrees with your editorial view that "a campaign of education cannot diminish the incidence" of cancer. Personally I think his arguments regarding the kangri basket of Kashmir and the betel nut habit of the Philippine Islands are irrefutable.

Now in this country the crucial question involved is whether or no there be pre-cancerous conditions. On this point the writings of many of your contributors are pretty clear, and a recent example is afforded by the article of Dr. Ernest Shaw in your issue of Feb. 3rd. He writes : "In view of the known fact that cancer arises in the great majority of cases in a breast already altered by inflammatory action the small operation of local removal would prevent the formation of cancer in a great many women." I think the large majority of surgeons will endorse this opinion and they consider the removal of the breast for degenerative mastitis one step in the fight against cancer. No less an authority than Sir Lenthal Cheatle has emphasised the importance of this aspect of the case, though he prefers the word "proemial" to "pre-cancerous."[1] The point remaining is whether a publicity campaign will induce women with mastitis to submit to surgery. Personally I think it will be of the greatest help.

There is another direction in which I should like to plead for a change of the editorial mind. You apparently object to the word "control" with reference to education in cancer problems, but in the dictionary by my side I find as synonyms for "control," "to restrain, govern, overpower," and that is what we must surely hope to do with cancer, and at once. Let it certainly be granted that we cannot prevent a disease until we know its causation, but do not let us give up our effort to hinder its progress. At the Royal Society of Medicine on March 13th it is proposed to hold a discussion on the Urgent Need for Education in the Control of Cancer, official notice of which has, I expect, reached you by this time, and it is because I am to take part that I urge the acceptance of the word "control." Its value lies partly in the fact that it begins with the letter "c," partly because it is in use all over America, where the Society for the Control of Cancer claims to have already done good work, and lastly because it appears to be exactly the right expression.—I am, Sir, yours faithfully,

Harley-street, W., Feb. 12th. Joseph E. Adams.

GASTRIC ULCER AND GASTRIC CANCER.

To the Editor of The Lancet.

Sir,—Dr. A. C. Jordan, writing in your issue of Feb. 10th, states that a tense pylorus and a full pars pylorica are present in gastric ulcer and that the barium meal remains in the stomach for 50–70 hours in such cases. Surely, Dr. Jordan refers only to extensive and comparatively rare pyloric obstruction, usually due to carcinoma at the pylorus, and sometimes found also in very chronic duodenal ulcer close to that sphincter. In chronic gastric ulcer, where a penetrating lesion is present along the small curvature, or the posterior surface of the stomach, no such pyloric stenosis exists and the time of emptying shows no great delay, the meal completely passing out from 2–4 hours. In gastric ulcer, where no penetration is present, but only an incisura to indicate its site—that is to say, ulcer of a less extensive and chronic type—rapidity of emptying is the rule, often well under two hours. Even in ulcer situated at the pylorus, in the majority of patients, no delay in emptying is present. Only rarely is definite delay in emptying to be seen, and to rely upon such a sign to diagnose gastric ulcer must lead to inaccurate diagnosis in 99 per cent. of cases.

Dr. Jordan speaks also of "a distended duodenum in a state of active peristalsis in such cases, making strong efforts to overcome a stubborn duodeno-jejunal kink." A strongly contracting duodenal first stage is not dilated, the muscular contractions reducing its lumen. Also, a stomach with chronic ulcer at the upper portion of the fundus does not show hyperperistalsis of the duodenum. Hyperperistalsis is present in cases of gastric ulcer complicated by a duodenal lesion. I have seen such, and Lord Dawson reported one case about a year ago and mentioned that I had made the double diagnosis previous to operation. I have met this condition again since then. The incidence of such cases is usually given at 4 per cent. of all gastric patients operated on. This is probably a high estimate.

The duodeno-jejunal "kink" is present in every case of gastric ulcer, but also in normal cases, and its connexion with gastric ulcer is probably as remote as its pathological existence ; unless Dr. Jordan refers to the normal duodeno-jejunal flexure. Hyperperistalsis of the duodenum is usually found in duodenal ulceration. It is often associated with deformity of the bulb, either spasmodic or organic, which may range from a small incisura, constantly present, to a complete alteration of the normal duodenal shape. I have many radiographic examples of this at hand, but in 99 per cent. gastric delay in emptying was not present, rather the reverse, and the duodenum was not dilated, but contracted, hyperperistalsis and antiperistalsis being often present. Further, a closed pylorus means an empty duodenum and in pyloric stenosis the duodenum is very difficult to observe, being empty, or very sparsely filled with the opaque meal, and in such cases the duodeno-jejunal flexure is not visible, being hidden by a dilated pars pylorica and pars media. One wonders how Dr. Jordan observes the " kink " in such cases.

---

[1] Vide Brit. Med. Jour., June 3rd, 1922.

In his letter he also states, " In the large intestine will be found in every case ample evidence of old stasis." Some patients with gastric ulcer do not suffer from intestinal stasis, some do, but conversely, many people who have intestinal stasis do not have gastric ulcer and the relation is far from being established on facts. It would be interesting to have the opinion of other radiologists on this point. It is generally accepted that 75 per cent. of intestinal stasis is found in women, whilst 75 per cent. of chronic gastric and duodenal ulcers are found in men. These facts cannot be reconciled with Dr. Jordan's statements.

Unless a carcinomatous ulcer is of large size, it is difficult, almost impossible, for the radiologist to distinguish it from a benign, chronic penetrating ulcer of the small curvature, and this is, of course, an important point bearing upon the surgical treatment of these lesions, as opposed to the purely medical. Again I must differ from Dr. Jordan. In carcinoma of the stomach, unless of the pylorus, there is not usually, practically never, " a big, dropped pyloric portion, the tight pyloric spasm, &c.," and even in pyloric carcinoma the pylorus may be more patent than usual, the sphincter fibres having been replaced by the growth, thus leading to rapid passage of the meal into the duodenum.

Lastly, a large proportion of carcinomata of the stomach are not based upon chronic gastric ulcers, though I quite agree that some are. The symptoms carefully investigated date often from six weeks to three months. The disease appears often in very healthy, strong individuals, irrespective of sex, and as early as 26 years of age, and cannot generally be looked upon as " the final breakdown of diseased organism . . . that has lost its capacity to resist malign influences," as Dr. Jordan asserts.

I am, Sir, yours faithfully,
GEO. VILVANDRÉ, M.R.C.S., L.R.C.P.,
Feb. 13th. Assistant Radiologist, London Hospital.

ALCOHOL AND INSANITY.

To the Editor of THE LANCET.

SIR,—In your leading article on alcohol and insanity in THE LANCET of Feb. 3rd, you say: " Thus it will be seen that the results of the mass experiment of the war have completely confirmed the view that intemperance is not . . . an important factor in the general causation of mental disease." While I agree that it is not, I must emphatically deny that any evidence adduced in your leading article proves it. It is said that although during the war alcoholism diminished, the incidence of insanity in females did not diminish but actually slightly increased. Such an observation is in itself valueless. I suppose nobody maintains that alcohol is the sole cause of mental disease, so that, granted that insanity rose while alcoholism fell, that is only significant if it be shown that at the same time other causes of insanity did not increase to a greater degree than alcoholism decreased. So far as your article indicates, no attempt was made to exclude such increased action of other factors, although the presumption must be that they did actually exist and to a very much greater degree than in pre-war days.

I am, Sir, yours faithfully,
Wimpole-street, W., Feb. 9th. STANLEY WYARD.

L'AFFAIRE SPAHLINGER.

To the Editor of THE LANCET.

SIR,—Your impartial review of some of the facts relating to this subject shows a generous attempt to solve a most perplexing problem, and will, I hope, lead to further discussion and elucidation. My personal interest was stimulated by the fact that a neighbour—an advanced case of pulmonary tuberculosis—secured some of Spahlinger's partial sera and asked me to take charge of him. With the approval of Dr. Clive Riviere, who had been looking after him, and the consent of the local practitioner, I undertook to do so. I have since made use of the opportunity, available to all medical men, to examine some of the cases treated in London in 1913–14, to look through the reports both of these and many other cases treated in Switzerland and France, and have spent three days in Geneva studying with Mr. Spahlinger details of his theory and technique and many cases now under treatment.

Briefly, the result of my investigation is this: My own patient is much better—dyspnœa practically disappeared, temperature fallen 1½°, dullness diminished, few dry crepitations where there were abundant moist râles, T.B. in sputum. Of the cases vaccinated in 1913–14, of which I saw ten (including one lupus, two glands, one bone case), one only showed evidence of recurrence. This was a case reported in 1913 as advanced pulmonary tuberculosis. He is now doing hard work as a gas-mantle maker. There is no sign of active disease in his lungs, but he has necrosis of the right superior maxilla. It should be noted in this connexion that Spahlinger has never claimed to produce more than 6–7 years' immunity by his vaccine, and that this man is living in unhealthy surroundings with his mother who is a chronic consumptive. The cases being now treated with partial sera in Geneva, most of them discharged from sanatoria as incurable, could not fail to impress the most sceptical. They describe their progress in the relief of symptoms—dyspnœa, debility, pyrexia, sweats, emaciation, &c.—as miraculous, and they certainly all look and seem remarkably well, though they are not cured.

May I then venture to offer a few criticisms on the points in your leading article in last week's issue? No statement is made in the memorandum to which you refer that the reports *already published* prove the national importance of the movement. What is claimed is that the names, actions or reports of those referred to in the memorandum support such a contention, for it must be known to you that one of the difficulties to be faced is that, though the published reports are meagre, the reports marked " private for scientific purposes only " are really the most convincing. Is no weight to be attached to the note of F.R.C.P., one of our most eminent authorities on diseases of the chest? I have had the opportunity of seeing lately some of the patients who had Spahlinger's antituberculous treatment and vaccination in 1913–14. Six years back they were affected with extensive tuberculous lesions, some of them with cavities. Since the end of 1914 these patients have had no treatment whatever. Re-examined in 1920 they showed fibrotic change in the lung and no trace of active tuberculosis, no cough, no sputum. These patients are in perfect health and able to carry on their daily occupations. Spahlinger's vaccine treatment for tuberculosis seems most effective in completing and maintaining the antituberculous cure, as all the patients examined have had no relapse during a period of over six years.

You regard the statement that there is evidence that Spahlinger's vaccines will prevent tuberculosis as exaggeration, yet his early experiments on the prevention and cure of tuberculosis in guinea-pigs are well known and supported, and he permits me to publish the following facts on his experiments on cows. Nine Freiburg cows, which did not react to tuberculin, were vaccinated in 1916, over a period of six months. In 1917 each was inoculated in the shoulder with a large quantity of a culture of virulent living bovine T.B. Large abscesses formed at site of injection. Both cultures and pus from abscesses killed guinea-pigs in eight to nine weeks. Abscesses gradually healed, leaving indurated skin adherent to subcutaneous tissue. 1918: Two cows killed in presence of veterinary inspector for Geneva. No evidence of tuberculosis—macroscopic, microscopic, or bacteriological—and meat allowed to be sold for food. 1919: Two more killed, same result. 1921: One more killed, same result. The other four are alive in perfect health and condition, and will be killed in turn. In 1916 also he purchased a cow which showed marked tuberculin reaction. She had a bad cough and pronounced wasting. She was vaccinated and is now free from cough and a fine healthy looking cow.

What is to be done? Independent investigation of clinical cases in England and Switzerland would be welcomed by Mr. Spahlinger and everyone acquainted with the facts—but investigations in research laboratories are impossible at present, as there is no supply of the complete serum, and no partial serum has been found effectual in protecting animals so susceptible to tuberculosis as guinea-pigs. Mr. Spahlinger and his family have given all they have and can do no more. Much of the work, such as the immunisation of horses has been relinquished, and unless financial help is forthcoming he will abandon the work.

Must we wait for bacteriological demonstration, or can we fairly claim that the impressive, positive, clinical evidence already available is sufficient justification for asking for financial help in England, are questions, therefore, on which the medical men interested will anxiously await your opinion and guidance.—I am, Sir, yours faithfully,

H. S. Wansbrough Jones, M.B., B.Sc.

Stede Court, Biddenden, Kent, Feb. 17th, 1923.

VACCINE TREATMENT IN PERNICIOUS ANÆMIA.

To the Editor of The Lancet.

Sir,—Dr. P. N. Panton, Dr. A. G. Maitland-Jones, and Dr. G. Riddoch, in their analysis of 117 cases of pernicious anæmia, which appeared in The Lancet of Feb. 10th, "take the strongest possible exception" to our recommendation to use autogenous vaccines in the treatment of the disease. They give no reason for this beyond stating that they "fail to find any justification for such a procedure." If they had read a lecture published by one of us in your issue of Jan. 20th they would have discovered the justification. Briefly stated, it is as follows. In a series of 14 cases of pernicious anæmia and subacute combined degeneration of the spinal cord the *Streptococcus longus* has been isolated in every instance from the duodenal contents, obtained through an Einhorn tube with the strictest precautions to void contamination. In the more recent cases, in which the question has been specially studied, the streptococcus has been found by Dr. F. A. Knott to be hæmolytic. Similar investigations on the duodenal contents of four normal individuals and 51 patients suffering from various disorders, excluding pernicious anæmia, have shown the presence of streptococci in six instances only, and in these the streptococcus was not hæmolytic. The difference is not simply due to the achlorhydria, which was present in all the anæmic cases, as achlorhydria was also present in seven of the others, and in these no streptococci were found. The striking contrast between the 100 per cent. cases of pernicious anæmia and the 11 per cent. other cases with streptococci in their duodenal contents is at least suggestive that a streptococcal infection of the intestines may lead to the production of hæmolytic and neurotoxic poisons, the absorption of which gives rise to the anæmia and spinal degeneration respectively.

There is thus a more solid experimental foundation for the use of a vaccine prepared from the patient's own duodenal streptococcus than for any of the other methods of treatment mentioned by Dr. Panton and his colleagues, with the exception of the use of large doses of hydrochloric acid, which they admit seems "worthy of trial." Too short a time has passed to be able to state definitely whether the vaccine treatment is of real value. But we can say without hesitation that it has never done harm, and our impression is that it has proved of material advantage when combined with the removal of oral sepsis and the use of hydrochloric acid in large doses in an attempt to overcome the underlying infection, whilst the use of arsenic and, in spite of the doubts of Dr. Panton and his colleagues, repeated transfusions have helped to relieve the anæmia which results from the infection.

In a disease like pernicious anæmia, which according to Drs. Panton, Maitland-Jones, and Riddoch is almost invariably fatal, is it not worth while giving every method of treatment which is based on reasonable grounds a fair trial? Until they can suggest some rational alternative of proved value, their criticism appears to us to be quite unjustified.

We are, Sir, yours faithfully,

Arthur F. Hurst.
J. R. Bell.

New Lodge Clinic, Windsor Forest, Feb. 12th, 1923.

DEATH CERTIFICATES AND THE CORONER.

To the Editor of The Lancet.

Sir,—I read recently in the press that in a case in which a house surgeon had given, or offered to give, a death certificate, a woman having died half an hour after admission to hospital, the coroner said the attendance was not long enough to warrant a certificate. Twenty-five years ago, as house physician, I had a somewhat similar experience. The late Mr. Braxton Hicks then censured me at an inquest, at which I was not present, for giving a death certificate in the case of a child suffering from pneumonia, who was under my personal care for four hours in a special ward of the out-patient department, awaiting removal as the hospital was full. The child died next day, at home. The coroner made this pronouncement, "That one visit did not constitute a medical attendance." If one visit does not constitute a medical attendance—what does?—I am, Sir, yours faithfully,

Orsett, Essex, Feb. 12th, 1923. Walter Allingham.

SOME CARDIAC QUESTIONS.

To the Editor of The Lancet.

Sir,—The paper by Dr. John Cowan and Dr. J. K. Rennie on the Causes of Death in Chronic Valvular Disease of the Heart in The Lancet of Feb. 3rd, draws attention, it appears to me, to one feature of importance in cardiac disease, but in other cases there may be a misinterpretation of post-mortem records.

In children, and in some cases of young adults, the fatal ending is due to a fresh attack of rheumatism affecting the heart, mainly the cardiac muscle. For this reason I have always maintained that it is unnecessary to restrain the activities of a child with a cardiac valvular lesion. Unless exercise is carried to the point of fatigue, which fatigue may predispose to fresh attacks of rheumatism, it seems to me that restraint may entail undue hardship on a child. Apart, however, from the recent endocarditis of rheumatism in fatal cases of chronic valvular disease, my own feeling is that Dr. Cowan and Dr. Rennie have been misled by appearances. When engaged in post-mortem work it always appeared to me that the frequently repeated statement that infective endocarditis attacks diseased rather than healthy valves is due to a partial misunderstanding of the nature of infective endocarditis. Infective endocarditis may sometimes—in fact, not very infrequently—deserve the name of a chronic disease, and lead to fibrosis of valves. The appearance of this fibrosis, when in the mitral valve, for example, is, however, quite different from that of the fibrosis due to rheumatism. The fibrosis of rheumatism is uniformly spread over the valve and chordæ tendineæ, leading eventually to mitral stenosis, while that of infective endocarditis is irregular and causes puckering. I cannot say that my experience supports the view that infective endocarditis is anything but quite an exceptional ending in cases of chronic valvular disease.

I feel tempted to refer also to Dr. Martin Raven's paper in the same issue, in which he speaks of the disappearance of a diastolic bruit at the apex of the heart after acute rheumatism occurring in children. It is unfortunate that there should still appear to be so widespread a misunderstanding concerning the importance of this common sound. It has no connexion whatever with the presystolic murmur which may sometimes follow it. Vegetations never arise in rheumatism of a size which could produce such a sound, nor explain the disappearance of the sound by disappearing themselves.

I am, Sir, yours faithfully,
Norwich, Feb. 15th, 1923. THEODORE FISHER.

AUTO-INTOXICATION OR DEMENTIA PRÆCOX?

To the Editor of THE LANCET.

SIR,—While on duty with the U.S. Public Health Service in London during the summer of 1921 a case of apparent dementia præcox came under my observation, a report of which I hope may be of interest to your readers.

The patient had been in one of the first detachments of the U.S. Army to go to France in the spring of 1918. His service was said to have been good until the spring of 1919, when he became careless in his work and unreliable in the execution of orders. On his return to the States in the summer of 1919 with his detachment he was demobilised with a diagnosis of dementia præcox and sent to a hospital for further care and observation, expenses being paid by the Veterans' Bureau. After a stay there of eight months the diagnosis of dementia præcox was confirmed by the medical officer in the hospital, who gave a hopeless prognosis. He was taken from hospital and finally brought to England in June, 1921. He came under my observation in London in July, 1921. The physical examination was negative, save for increased knee-jerks, all other reflexes being apparently normal, no glandular enlargements or evidence of any specific infection, negative Wassermann. In conversation with him there was an apparent inability for fixed attention and connected thought. His replies to all questions were clear enough, but for one who had travelled extensively and who had done so great an amount of work requiring the utmost thought and concentration, they showed that some profound mental change had taken place. The attendant reported that he complained of recurrent headaches, while he had frequent outbursts of temper from very trivial causes. He also suffered from persistent sleeplessness. He is rather a good draughtsman. I was shown some of the sketches made during his hours of wakefulness. Figures of women with few clothes or none at all in varying states of abandon were the products of his sleepless hours. These pictures were obscene. The malady appeared to be dementia præcox and I gave a hopeless prognosis to his family, and advised exercise, cascara, and reading.

In August I met Dr. Uhrstein, of Warsaw, on his return from the United States, where he had been representing the Polish Government on an important mission. Dr. Uhrstein was formerly in the Russian Army, and is very well known on the continent as a specialist in nervous diseases and especially on account of his many papers on dementia præcox. It seemed a happy thought to tell Dr. Uhrstein of this case, and request a visit and his opinion. This was done, and he very gladly called with me on the patient. A very thorough examination by him showed nothing more than had been found in my previous visits. Dr. Uhrstein confirmed the diagnosis and advised exercise, cold baths, and a testicular extract made in the States. There was no improvement, fits of temper continued to come on from time to time, while the making of lewd pictures continued.

In September of 1921 I talked with Dr. A. S. Woodwark of the case, and he very kindly agreed to see the patient with me. At this time I had advised a nursing home, and the Veterans' Bureau at Washington had agreed to care for the patient in such an institution. After his examination, Dr. Woodwark said he would not give an opinion until he had had an opportunity of more extensive observation, but agreed with me that the patient should go into a nursing home for a time. The patient broke up this carefully matured plan by flatly refusing to go to any nursing home. More headaches, more sleepless nights, more temper, and more pictures followed. At my wits end, knowing that he had suffered for a long time from advanced intestinal stasis, to which condition I have devoted several months of close study and observation of cases before and after operation, the idea of liquid paraffin came to me, in the hope that the headaches and general condition would be improved by its regular use. A tablespoonful night and morning was ordered. This was in November, 1921. Very soon after reports of improvements began to reach me, headaches were less frequent, he slept better, he took more interest and zest in his daily exercise, and I was not sent for. In January the patient burned all of his artistic achievements, broke up his drafting table, and threw away his beautifully sharpened pencils, and began to talk of getting to work.

In February he made a visit of several weeks to the Continent, unaccompanied by his attendant. He returned in a condition like that which had preceded the use of paraffin. His family were in a hopeless state of discouragement, all apparent promise for recovery being gone. On learning that the paraffin had been discontinued during his trip, I gave it as my opinion that his present condition was a result to be expected from his failure to take the oil, and that a resumption of its use in still greater doses would be followed by an improvement such as had been seen in the previous autumn. Happily this opinion has been proved to be right; 11 months of constant use of liquid paraffin has apparently brought the patient back to his normal condition. He is doing a great deal of work requiring a very high order of mental effort, and doing it on his own initiative with no direction from anyone.

Whether this is a case of dementia præcox with its manifestations greatly increased by the absorption of intestinal toxins, or one in which the symptoms of this disease have been simulated from the consequences of chronic intestinal stasis, I will leave it to the reader to decide.—I am, Sir, yours faithfully,

BURR FERGUSON,
A.A. Surgeon.
Treasury Department, U.S. Public Health Service,
Southampton, England.

THE OPPOSITION TO PANEL PRACTICE.

To the Editor of THE LANCET.

SIR,—There is a statement in THE LANCET of Feb. 17th which ought not to go unchallenged.

> "It may be admitted, however, that a certain number of insured persons do go to private practitioners and pay fees. This is due, on the one hand, *to the fact that in London there exist a certain number of non-panel doctors who, being hostile to the Act, persuade patients that they get better treatment by attendance as private patients*; and, on the other hand, to the idiosyncrasies of the patients themselves."

A very large number of patients, who from time to time come under the Act, prefer to retain the services of their own non-panel doctor. A very large number of patients leave their panel doctor and pay fees. In both these cases the patients generally refuse to go to the trouble of "making other arrangements" because of the great difficulty which is always thrown in the way of doing so. Their names are nearly always included in the list of one or other panel doctor for the convenience of obtaining certain certificates. On this account statistics are useless.

The statement, which I have italicised, is quite untrue. It imputes dishonourable acts to non-panel doctors and tends to create bad feeling. I have noted that for some time now THE LANCET has adopted an attitude which is definitely hostile to doctors who are general practitioners and not on the panel. I am, Sir, yours faithfully,

S. G. ASKEY, M.A., M.D.

Balham High-road, S.W., Feb. 19th, 1923.

*** We have not the attitude imputed to us, nor were the italicized words, which we agree were not happily chosen, meant to convey what our correspondent sees in them.—ED. L.

THE BACTERIUM PNEUMOSINTES.

To the Editor of THE LANCET.

SIR,—In connexion with the question of the filter-passing properties of organisms causing influenza, I should like to draw attention to the fact (verified continuously under all sorts of conditions by the late A. S. Leyton and myself) that macroscopic organisms can give off ultramicroscopic spores. This was proved in the case of the streptothrix group, three to six months' old cultures giving off exospores which will pass both F. and B. Chamberland candles.[1] Therefore, the fact of macroscopic organisms developing from cultures of filtered material does not imply contamination if the culture is a pure one. The morphological appearance of the *B. influenzæ*, especially the strepto-bacillary and involution forms, are in themselves suggestive of spore formation.

I am, Sir, yours faithfully,

Cambridge, Feb. 15th, 1923. HELEN G. LEYTON.

THE DISPENSING OF PRESCRIPTIONS.

To the Editor of THE LANCET.

SIR,—While interested in the leading article of your issue of Feb. 17th on substitutes or equivalents in prescriptions, I thought it would be of general interest to the readers of THE LANCET, a paper which has always been to the forefront in matters such as adulterations, &c., to know the results of an investigation recently made in this borough.

An opportunity was taken of having quite a simple prescription dispensed by chemists, and as far as we have gone with it, and another equally simple, 17 chemists being tried, six have fallen far short of accuracy. This can only point to careless dispensing. The prescription was *not* an insurance one. One looks for better results than this from the pharmacist, for the price paid for dispensing is considered to be in some degree a payment for skill, as it exceeds considerably what would be considered a reasonable profit on the cost of the ingredients. Surely, when over a third are so lax in their methods as has been stated (I have taken no account of slight discrepancies) there must be something radically wrong. At this time, when so many charges are being made against the panel doctor, it is as well that he should know what chance his patient has, or the non-panel doctor's patient has, of the medicine he prescribes being properly dispensed.—I am, Sir, yours faithfully,

G. CLARK TROTTER,
Medical Officer of Health, Islington.

Feb. 19th, 1923.

POST-OPERATIVE "MANIA."

To the Editor of THE LANCET.

SIR,—Prof. G. M. Robertson has mistaken the object of my remarks. This was to call attention to a mental condition, occurring most unexpectedly after an ordinary operation, alarming both in its quick appearance and its mode of advance. Hence I did not go into the special points to which he refers. I also wished to draw attention to treatment, which need not be of the asylum order.

I am, Sir, yours faithfully,

Folkestone, Feb. 12th, 1923. W. J. TYSON.

---

[1] Particulars may be found in the Journal of Pathology and Bacteriology, vol. xxi.

Public Health Services.

REMEDIAL WORK FOR INSURED PATIENTS.

A CASE has been considered recently by a panel committee in which remedial work was suggested by the doctor for his patient whilst still in receipt of sickness benefit. The case was one of concussion, with loss of memory and inability to concentrate, in which after five weeks' complete rest the doctor advised the patient to occupy herself with small tasks and recommended light house duties. The approved society replied by quoting their rule "that no member is allowed to do any form of work when on the sick funds." The society regarded such action as a breach of their rules and as interference on the part of the doctor with the administration of benefits, this function belonging to the approved society alone. The panel committee referred the question to the Ministry of Health with the hope that remedial work for persons in receipt of sick benefit would be placed on a regular footing. The question is an important one, for if the administrative difficulties of approved societies can be overcome some kind of occupation for body and mind would materially help the restoration of many an insured person to working efficiency after a period of sickness. The question has been solved in the case of tuberculous insured persons who are residents in a colony such as Papworth. In such a community the supervision of the medical officers is regarded as a sufficient safeguard by certain approved societies. In ordinary cases where the insured person is treated at home the societies have no such safeguard, and they are not ready to relax their necessarily rigid rules.

Notwithstanding these difficulties it is important that the value of remedial work should be recognised. In the more arduous occupations the insured person's health and strength must be of a high order, and after acute illness it might be dangerous to put such a severe strain on the impoverished system as the full day's work would involve. The human frame cannot suddenly be called upon to endure the strain involved in the change from complete inaction to complete activity such as the occupation requires. For this reason, after a prolonged period of convalescence, the doctor recommends resumption of light work. In most cases such a recommendation is futile, for the moment the patient returns to work he must be prepared to put in a full day's heavy toil. The result may be disastrous, involving permanent damage and weakness to vital organs. If the convalescent period could be occupied by some form of remedial work, graduated in such a manner as to train the muscles and vital organs to a measure of activity short of dangerous strain, not only might the period of convalescence be shortened, but the restoration of mental balance would be accelerated by the happiness of the patient who is sick of inactivity. Furthermore, such remedial work would furnish a very practical test of the patient's capability or otherwise to follow his usual occupation.

If remedial work is possible in certain forms of sickness, such as tuberculosis, we fail to see why adequate supervision should not be possible in all acute illness. But it implies confidence between the doctor and the approved society.

AFTERMATH OF THE GUILDHALL CONFERENCE.

It is increasingly evident that the conference of the insurance medical service, held at the Guildhall on Jan. 30th and 31st, has helped to clear the air. The *Insurance Gazette* is satisfied that the hesitancy felt by some of the approved societies in taking part in the conference was not justified by the result. "Things were said by society representatives which could hardly commend themselves to the doctors, but there was a spirit of mutual forbearance, and this frank exchange of view did no harm. . . . The atmosphere soon became friendly, though this did not prevent the complaints and criticisms of all sections being quite outspoken." The *Gazette* anticipates that a real attempt will be made to meet the points raised by the societies. The medical profession must regard with satisfaction the demonstration that there are many genuine enthusiasts on the lay side among the National Health Insurance workers, and it should be possible by real coöperation to solve many of the difficulties which now interfere with the smooth working of the Acts. As Sir Alfred Warren said in the conference : " One great augury of good is that some of them, having been firing at long range ever since the first Act came into operation, have now realised the value of the conference table." The *Gazette* declares that " it is a good start on a good road, and we offer congratulations to those responsible for it."

From the detailed reports of the conference now available it seems that there was very general feeling that the panel system is worth preserving and making more efficient, and that the suggestion of a whole-time salaried service being in any sense a better one met with scant support. The present machinery was felt to be sufficient, if properly worked, to deal with the majority of the complaints.

Obituary.

WILLIAM JAMES AITKEN QUINE, M.B., B.S. LOND., D.P.H.

Dr. Aitken Quine died in a nursing home at Plymouth on Feb. 17th after undergoing a serious operation earlier in the week. He was 35 years of age and was on the point of taking up his new appointment as port medical officer for Plymouth. A Manchester student, qualifying in 1913, he was resident at the Monsall Fever Hospital when the war broke out, and he obtained a commission as surgeon-lieutenant in the Navy. He was on H.M.S. *Calliope* in the battle of Jutland and for nearly 48 hours in sole medical charge, his superior officer having been severely wounded. After the armistice he settled at Chinley, Derbyshire, where he built up an extensive practice and was medical officer to the county venereal clinic. His early death is grievously felt.

THE LATE DR. G. A. W. SPEAR.

Mr. A. E. Mortimer Woolf writes : Dr. G. A. W. Spear, whose death you recorded in a brief notice in THE LANCET of Feb. 10th, had a personality which was the embodiment of cheeriness, combined with a thorough knowledge of his work, which he applied with the maximum of good sense. Courteous to all, kindly and considerate to rich and poor alike, it was not surprising that he was regarded as the personal friend as well as the family doctor by his patients. At the outbreak of war he joined immediately, and was for a time in command of the hospital at Shoeburyness, where he was universally beloved. If there was difficulty in getting a particular squad of men inoculated, Spear almost always succeeded in obtaining their consent. Subsequently he served in Egypt. His outlook on life, apart from his professional interests, was that of friendship. He had that uncommon knack of imparting a piece of himself to those with whom he was talking. The spirit of the man was never better shown than in the way he bore his last illness. Stricken by a painful fatal disease, his thought for others never deserted him, till his death at the early age of 47.

THE LATE MR. HUNTER TOD.

To a large gathering of the members of the Section of Otology of the Royal Society of Medicine and several personal friends Sir Charles Ballance read an appreciative notice of their late President, Mr. Hunter Tod, who died while holding the office.

" It was my privilege," he said, " to know our President well, both in his professional and private life, and I deeply mourn the loss of my friend. During the last few years he was often in my house, and on each occasion a merry freshness and happiness seemed to emanate from his presence. A visit from Hunter Tod was ever a welcome tonic, for he was one of those who ' Make undying music in the world.' He revelled in the game of life. He played it from start to finish right strenuously and with zeal and enthusiasm like a knight of the olden time. Incidentally, I may mention that his fighting instincts were often used with success to increase the prestige of our specialty ; while his intellectual gifts, his wide range of clinical experience, and his skill as an operator were devoted to the science and art he loved so well. During all the long and painful illness of our President no word of complaint ever passed his lips. His courage mounted with occasion : it was of that type which never submits and never yields. Even to the last he met me with a smile."

The Services.

ROYAL ARMY MEDICAL CORPS.

Maj. and Bt. Lt.-Col. F. D. G. Howell relinquishes the temp. rank of Lt.-Col. on ceasing to be empld. as Asst. Dir. of Hygiene.

Maj. J. A. Clark is restd. to the estabt. and relinquishes the temp. rank of Lt.-Col.

The undermentioned Majs. retire on ret. pay : J. A. W. Webster and J. H. Duguid.

Temp. Capt. S. Herbert relinquishes his commn. on account of ill-health contracted on active service and retains the rank of Capt.

TERRITORIAL ARMY.

Maj. J. W. Kemp to be Lt.-Col. and to command 56th (1st London) Casualty Clearing Station.

Maj. E. L. Rowse, having attained the age limit, is retired, and is granted the rank of Lt.-Col.

Capt. W. T. D. Mart resigns his commn. and is granted the rank of Maj.

Capts. F. R. Harris and R. Henry to be Majs. (prov.).

Capt. E. H. Mayhew (late King's African Rifles) to be Lt. and relinquishes the rank of Capt.

Capts. J. Wallace, from T.A. Res., and D. P. H. Gardiner (late R.A.M.C., T.A.) to be Capts. ; and Capt. P. Hickey to be Lt.

Capt. D. R. Cramb relinquishes his commn. and retains the rank of Capt.

General Hospitals : The undermentioned, having attained the age limit, are retired and retain their rank, except where otherwise stated : Lt.-Cols. P. Mitchell, J. M. Booth, R. Pratt, W. H. B. Brook, F. S. Lambert, W. S. Porter, A. J. Hall, and J. S. White ; Majs. R. W. W. Henry (Bt. Lt.-Col.), F. S. Genney (granted the rank of Lt.-Col.), R. G. McKerron, G. Gibb, A. R. Galloway, C. H. Usher, D. W. Geddie, R. Sevestre, J. T. H. Davies, H. J. Blakesley, C. E. Marriot, J. S. Sloane, J. D. Slight, R. Stewart, C. B. Turner, O. H. Chapman, B. McFarland, G. Wilkinson, G. H. Pooley, and A. E. Naish ; Capts. E. S. Winter (Bt. Maj.), G. J. R. Lowe (granted the rank of Maj.), J. R. Levack (granted the rank of Maj.), A. Young, J. M. P. Crombie, A. M. Stalker, J. M. Whyte, G. M. Duncan, J. Taylor, A. E. Payne, A. M. Crosfield, A. Foster, R. B. Stamford, E. L. Lilley, R. R. Young, J. W. Patrick, R. Michell, F. W. Bennett, R. H. Fagge, W. M. Holmes, E. W. Holyoak, H. Mason, A. Burgess, R. E. E. South, A. Miller, O. Giles, G. L. H. Revill, C. J. Coleman, D. E. Darbyshire, P. W. Young, J. B. Hall, W. Billington, J. A. Blayney, J. W. Walker, W. Scattety (granted the rank of Lt.-Col.), W. Gough, N. Milner, J. Broadley, G. S. Simpson (granted the rank of Maj.), W. J. N. Vincent (granted the rank of Lt.-Col.), H. J. E. H. Williams, M. Connon, J. E. Waite, and F. B. Carter.

The undermentioned relinquish their commns. and retain their rank except where otherwise stated : Majs. G. G, Turner, J. A. Coupland, G. E. Gask (granted the rank of Col.), and A. G. Yates ; Capts. A. E. Barnes (granted the rank of Maj.), L. R. Braithwaite (granted the rank of Maj.). W. H. G. Ball, F. W. M. Greaves, J. B. Lockerbie, A. Richardson, H. C. Snell, H. J. Macvean, and W. H. N. White.

ROYAL AIR FORCE.

G. R. Nodwell is granted a short service commission as a Flying Officer.

INDIAN MEDICAL SERVICE.

The King has approved of the retirement of Maj.-Gen. J. B. Smith and Lt.-Col. E. C. McLeod.

Lt.-Col. P. F. Chapman to be Col., and Lt. E. Kean to be Capt.

Medical News.

University of Oxford.—Theses submitted for the degree of Doctor of Medicine by William Seigfried Dawson, Trinity College, and David George Turner Kerr Cross, St. John's College, have been approved.

Royal Colleges of Physicians of London and Surgeons of England.—As the result of the Final Examination held from Jan. 9th to Feb. 2nd the undermentioned candidates were approved in the subjects specified :—

Medicine.—F. G. Allan, St. Thomas's ; Katharine M. Andrew and Constance E. Appleton, King's Coll. ; E. W. Arndt, Ceylon and Middlesex ; M. K. Barnett, Birmingham ; Jessie H. Baxter, Univ. Coll. ; A. Beauchamp, Birmingham ; J. S. Benzecry, Univ. Coll. ; Susanna M. Bernard and Margery G. Blackie, Royal Free ; J. C. Bose, Baltimore ; C. G. Bowen, Guy's ; J. F. Brailsford, Birmingham ; Enid A. Brock, Liverpool ; F. Brockington, King's Coll. ; Helen Bumstead, Charing Cross ; J. T. Burrell, London ; Viola C. Cameron, St. Mary's ; R. H. Carter, London ; L. Cohen, Leeds ; R. S. Coldrey, St. Bart.'s ; Eva D. Cook, Royal Free ; S. H. Cookson and W. Dabbs, Birmingham ; W. L. Dunlop, Liverpool ; H. T. Edmunds, King's Coll. ; D. G. M. Edwards, Univ. Coll. ; H. C. Edwards, King's Coll. ; L. C. J. Edwards, London ; A. J. C. Eland, St. Bart.'s ; G. M. Evans, St. Thomas's ; Valentine F. Farr, St. Bart.'s ; Margaret Findlay, Royal Free ; Annie Foner, Univ. Coll. ; F. W. Furniss, King's Coll. ; P. C. C. Garnham, St. Bart.'s ; C. E. Gautier-Smith, St. Thomas's ; Lena B. Gayer, London ; L. Ghabrial, King's Coll. ; G. N. Golden and S. J. Golden, London ; A. W. Gott and Marion Greaves, Leeds ; J. R. Hamerton, St. Bart.'s ; N. G. Harris, St. Thomas's ; J. S. Hawes, London ; Nancy W. Holloway, Univ. Coll. ; D. H. Hubbs, Guy's ; Audrey M. Hughes, Charing Cross ; Laura M. Jacobs, St. Mary's ; J. Jemson, Guy's ; Hilda M. Kennedy, Univ. Coll. ; E. H. Koerner, Guy's ; L. P. Lockhart, St. Thomas's ; Marian Lones and Kate Madders, Univ. Coll. ; Edith T. Marshall, Royal Free ; W. H. Marston, Birmingham ; Dorothy E. Mason, St. Mary's ; H. R. Matthews, St. George's ; Margarethe Mautner, St. Mary's ; Margaret S. Mills, Royal Free ; M. Mitman, Guy's ; Violet E. M. Mizen and Elspeth B. Moffat, Royal Free ; W. B. R. Monteith, Univ. Coll. ; J. H. Moorhouse, Liverpool ; Muriel L. M. Northcote, Royal Free ; Nancy B. Ockenden, Univ. Coll. ; Beryl Palmer-Jones, King's Coll. ; C. M. Pearce, St. Bart.'s ; T. V. Pearce, St. Thomas's ; J. P. Peel, Leeds ; A. F. Percy, Guy's ; J. W. Perkins, St. Mary's ; T. H. I. Potts, Sheffield ; Gertrude E. Pugmire, Liverpool ; C. K. Rau, Middlesex ; Dorothy M. Rees, King's Coll. ; R. P. Rees, Middlesex ; May Kathleen Ruddy, Charing Cross ; Edna M. Sanders, King's Coll. ; D. H. Sarafian, Middlesex ; B. E. Schlesinger, Univ. Coll. ; A. T. Schofield, Cambridge and St. Mary's ; J. H. Simpkiss, Birmingham ; G. Fraser Smith, Middlesex ; R. W. Smith, St. George's ; C. F. V. Smout, Birmingham ; S. S. Suzman, Guy's ; T. B. Thomas, St. Bart.'s ; G. K. Thornton, St. George's ; Olga F. Tregelles, St. Mary's ; E. G. L. Walker, St. Thomas's ; S. A. Walker, Liverpool ; R. Whillis, Univ. Coll. ; Ethel Whitby, King's Coll. ; M. C. Wilkinson, St. Thomas's ; L. A. Willmott, St. Bart.'s ; Edith V. Wood, London ; D. A. Woodeson, Liverpool ; and T. Wooldridge, Guy's.

Surgery.—J. C. Ainsworth-Davis and D. D. Anderson, St. Bart.'s ; Lucy T. Badcock, London ; H. P. Baylis, Guy's ; J. F. Brailsford, Birmingham ; T. F. Briggs, St. Thomas's ; B. Broadbent, St. Bart's ; W. A. Brown, Guy's ; Dorothy E. B. Buckmaster and J. T. Burrell, London ; J. R. Burrows, Liverpool ; J. E. Clegg, Manchester ; G. K. Cooper, St. Thomas's ; Florence E. Cowlin, Charing Cross ; R. S. Creed, St. Thomas's ; D. W. Crombie, London ; A. D. Dyson, St. Thomas's ; R. V. B. Emmons, St. Bart.'s ; S. W. Eveson, London ; R. A. Highmoor, Middlesex ; D. B. Hitchings, Guy's ; J. W. Hope-Simpson, St. Thomas's ; E. R. Hughes, London ; L. D. A. Hussey, King's Coll. ; R. Jackson, Middlesex ; N. A. Jery, St. Bart.'s ; J. I. Kelly, Manchester ; H. V. R. T. Lauder, St. Bart.'s ; M. M. Lewin, St. Thomas's ; L. O. Lindsay, London ; P. M. Lissack, St. Thomas's ; A. R. Lister, London ; N. L. Lloyd, Guy's ; C. A. Lupton, St. Thomas's ; C. C. Mahoney, St. Mary's ; L. Mather, Manchester ; J. W. Newbold, Univ. Coll ; M. Newfield, Charing Cross ; C. Ousep, Madras ; G. G. Penman, St. Thomas's ; Gwendolen M. Pratt, Royal Free ; Phyllis M. Rex, St. Mary's ; J. A. W. Roberton, St. Bart.'s ; May K. Ruddy, Charing Cross ; J. Russell, St. Thomas's ; J. M. Schofield, St. Mary's ; H. Seelenfreund and G. D. Shaw, Guy's ; H. H. Sumption, St. Mary's ; H. C. Suri, London ; R. G. Tame, Guy's ; A. S. H. Walford, St. Thomas's ; M. H. Webb-Peploe, St. Thomas's ; L. E. H. Whitby and A. K. Wiggins, Middlesex ; L. G. Williams, St. Thomas's ; B. B. Yodh, Bombay and London ; and L. S. V. Zinober, London.

Midwifery.—M. V. Abraham, Manchester ; P. M. Acheson, King's Coll. ; N. F. Adeney, Cambridge and St. Mary's ; F. G. Allan, St. Thomas's ; J. S. Alman, Berlin and Middlesex ; R. S. Anderson, St. Bart.'s ; C. E. Appleton, King's Coll. ; O. D. Ballinger, Oxford and St. Bart.'s ; A. A. Battson, St. Thomas's ; A. Beauchamp, Birmingham ; Susanna M. Bernard, Royal Free ; A. J. Boase, St. Thomas's ; E. R. Boland, Guy's ; H. A. Bond, Univ. Coll. ; J. C. Bose, Baltimore ; R. T. Brain, London ; J. A. Brew, Middlesex ; E. A. Brock, Liverpool ; R. Brooke, Guy's ; D. Brown, Liverpool ; J. W. Brown, Middlesex ; S. G. Brown, London ; W. A. Brown, Guy's ; B. H. Burns, St. George's ; J. R. Burrows, Liverpool ; L. C. Butler, Royal Free ; H. Cantrell, Liverpool ; N. E. Chadwick, St. Bart.'s ; G. D. Clarke, London ; J. M. Clarke, Otago and Middlesex ; L. Cohen, Leeds ; B. A. Coles, Westminster ; R. F. Connell, Middlesex ; G. G. Cooke, Birmingham ; G. J. V. Crosby, Univ. Coll. ; J. A. Currie, Guy's ; D. T. Davies, Cardiff ; J. S. Dees, Middlesex ; V. W. Dix, Cambridge and London ; A. J. Dodhi, Bombay ; N. B. Dreyer, St. Bart.'s ; H. M. Du Buisson, King's Coll. ; F. J. V. C. Ducoudre, Paris ; G. Dudley, Birmingham ; W. L. Dunlop, Liverpool ; W. P. Edmunds, King's Coll. ; G. Elliot, St. Bart.'s ; R. S. Ellis, Birmingham ; R. V. B. Williams, St. Bart.'s ; R. K. Wilson and R. E. Wilson, London ; M. M. E. Yate, Royal Free ; and B. B. Yodh, Bombay and London.

University of Bristol.—At examinations recently held the following candidates were successful :—

Final Examination for Degrees of M.B., Ch.B.

With Second-class Honours.—Francis J. Hector, Marguerite G. Hughes, Arthur J. Keevill, and Doris M. Pullen.

Part II. (completing examination).—Bertram A. Crook, John M. Evans, Frances M. Jones, James A. L. Roberts, Harry L. Shepherd, Hugh J. H. Spreadbury, and Frederick K. Wilson.

Part I. (including Forensic Medicine and Toxicology).—Sydney H. Blacker, Arthur P. Bodman, Ernest G. Bradbeer, Gilbert B. Bush, William L. Cossham, Mary F. Dalton, Frank R. Edbrooke, Norman J. England, Herbert M. Golding, William A. Gornall, John L. Griffin, Rowland C. Hatcher, Alexander G. Heron, Doris E. Joscelyne, Patrick C. Joscelyne, Edgar F. King, Arthur H. Marshall, John R. Nicholson-Lailey, Robert A. Sammons, Arthur E. Sherwell, Herbert Taylor, Robert E. Whitby, and Cecily F. Wilson.

Part I. only.—Naomi J. Bown, Helen M. Dixon, Lorna Dunn, and Prosper G. Evans.

Third Examination for Diploma in Dental Surgery.

Dental Mechanics (completing examination).—Gilbert C. Brooks and Cyril H. Hill.

Dental Materia Medica (completing examination).—Ernest W. Mogg.

Final Examination for Diploma in Dental Surgery.

Frank J. Farr, Herbert W. Pidgeon, Geoffrey G. Royal, Cyril G. Saxon, and Cecil R. Woods.

Examination for Diploma in Public Health.

Zaki Khalid.

Royal Sanitary Institute.—An evening reception is being held at the Institute, 90, Buckingham Palace-road, London, S.W., at 8.30 p.m., on Monday, Feb. 26th, to meet the medical officers visiting this country under the auspices of the health organisation of the League of Nations.

EPSOM COLLEGE.—The Council will shortly award "France" pensions of £30 a year to medical men. Candidates must not be less than 55 years of age, and their yearly income, independent of any allowance from the College, must not exceed £100. Application should be made to the secretary, Mr. J. Bernard Lamb, 49, Bedford-square, London, W.C. 1.

LONDON HOSPITAL MEDICAL COLLEGE.—A course of three lectures on Diabetes Mellitus will be delivered by Dr. Otto F. F. Leyton on March 19th, 20th, and 21st, at 4 P.M., in the anatomical theatre of the College. The course is intended for senior students of the hospital and post-graduates.

MIDDLESEX HOSPITAL MEDICAL SOCIETY.—The annual special meeting will be held at the hospital on March 6th, at 8.15 for 8.30 P.M. Dr. J. S. Haldane, F.R.S., will deliver an address entitled The Institutes of Medicine and Surgery. After the address there will be demonstrations on radium, X ray and electro-therapeutics, electro-cardiography, and bacteriology.

ROYAL INSTITUTION.—On Feb. 27th, at 3 P.M., Sir Arthur E. Shipley will deliver the first of two lectures at the Royal Institution on Life and its Rhythms; and on March 1st Mr. Theodore Stevens begins a course of two lectures on Water Power of the Empire. The Friday evening discourse on March 2nd will be delivered by Dr. G. C. Simpson on the Water in the Atmosphere, and on March 9th by Dr. C. W. Saleeby on Sunlight and Disease.

WELSH NATIONAL SCHOOL OF MEDICINE.—It is announced that the Privy Council proposes to reconstitute the National School of Medicine a separate Constituent College of the University of Wales, to be governed, under the University, by a Council and Senate of its own, as recommended in the Report of the Royal Commission on University Education in Wales. The views of many of the bodies who at the date of the Royal Commission's Report dissented from this portion of its recommendations are believed to have undergone substantial modification, and the National School may be congratulated on its near prospect of gaining independence.

CHILD-STUDY SOCIETY.—Among the lectures and discussions to be held at the house of the Royal Sanitary Institute, 90, Buckingham Palace-road, S.W. 1, under the auspices of this society, is one on the Sun and Open-Air School, to be delivered by Prof. Leonard Hill, F.R.S., on March 1st, Sir Henry Gauvain presiding; and one on the New Discipline, to be delivered by Dr. H. Crichton Miller on March 22nd, Rev. J. Scott Lidgett presiding. The lectures are held at 6 P.M.

UNIVERSITY OF MANCHESTER: GRAHAM RESEARCH LABORATORY.—The Council of the University of Manchester have approved a scheme for the establishment of a new laboratory for research in colloids. A sum of nearly £12,000 is available towards endowment and cost of equipment of the department, and the laboratory will be known as "The Graham Research Laboratory." Mr. D. C. Henry, at present lecturer in chemistry in the University, has been appointed lecturer in colloid physics from September next and will take charge of the laboratory.

OPHTHALMIA NEONATORUM IN THE METROPOLITAN AREA.—In THE LANCET of August 5th, 1922, we set out the numbers of cases of ophthalmia neonatorum notified in the metropolitan area in the years 1919, 1920, and 1921, and in the first half of the year 1922, noting the numbers of cases admitted to St. Margaret's Hospital for ophthalmia neonatorum for the same periods. The complete figures for 1922 are now available. The number of notifications (866) shows a decrease of 210 from the 1921 figure, whereas the 213 cases admitted to hospital correspond exactly with the number admitted in the previous year.

OXFORD OPHTHALMOLOGICAL CONGRESS.—This congress will assemble at Keble College, Oxford, on the evening of July 4th, and the meeting will be held on July 5th and 6th. On July 5th a discussion on the Relationship of Dental Sepsis to Diseases of the Eye will be opened by Mr. W. Lang and Mr. W. R. Ackland. The official dinner of the congress will take place in the evening. The Doyne Memorial Lecture will be delivered on the morning of July 6th by Mr. H. M. Traquair, the subject being the Differential Characters of Scotomata and Their Interpretation. Members willing to contribute papers, pathological specimens, new operations, cases or novelties of any kind, are asked to communicate with the hon. secretary, Mr. Bernard Cridland, Salisbury House, Wolverhampton.

AN IRISH TEMPORARY POOR-LAW BILL.—On the motion of Mr. Ernest Blythe, Minister for Local Government, the Local Government (Temporary Provisions) Bill has been given a second reading in Dail Earann. In his speech Mr. Blythe explained that the object of the Bill was to legalise the schemes already adopted in many counties without legal sanction. The Bill would expire on March 31st, 1924, and it was not intended that the existing schemes should remain in their present form even for that period. They would be altered and brought as near as possible to a standard form. Meanwhile, a comprehensive scheme of local government would be prepared, and it was hoped that it would become law long before the date fixed for the expiration of the Bill. The text of the Bill gives extensive powers to the Minister to vary and amend earlier existing schemes or schemes which may be adopted by counties in the future. In only one or two points does it appear to touch directly the interests of medical and other officers. (1) Under the Local Government (Ireland) Act of 1919, an officer of a local authority retiring under certain conditions might be granted by the local authority a pension not exceeding two-thirds of his salary and emoluments, without the authority being bound in any way by his years of service. The present Bill abolishes this right as regards the future, and as regards the amount of pension puts an officer back under the conditions laid down in the previous Superannuation Acts, by which his pension is limited by reference to his years of service. (2) The Bill gives the power to a county council to reopen the question of a pension awarded by the lessee (vanished) local authority to an officer compulsorily retired, and to have the pension fixed by the Minister. (3) The Bill provides that no person shall hold an office of profit under any local authority while he is, or within six months after he has ceased to be, a member of that or any other local authority. This interferes with the right given in certain county schemes to the medical profession of the county to nominate certain members of the county board of health, such members in some cases being employed as medical officers. With the Bill as printed is a valuable schedule setting out in full the schemes adopted in the several counties.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Reassembling of Parliament.

PARLIAMENT reassembled on Tuesday, Feb. 13th, the new session being opened by the King in person. In his speech from the Throne His Majesty, after a reference to the disturbed state of affairs on the Continent of Europe, and the efforts of the Government to secure peace in the Near East, said that reductions in public expenditure remained essential to the well-being of the State. After an assurance that unemployment and the condition of agriculture are engaging the attention of the Government, the speech went on to foreshadow legislation during the present session dealing, among other things, with the reform of local taxation, unemployment insurance benefit, housing, trade boards, industrial insurance, and rent restriction.

Dangerous Drugs and Poisons Bill.

A Bill to amend the Dangerous Drugs Act, 1920, and Section 17 of the Pharmacy Act, 1868, and to prescribe the method of calculating percentages in liquid preparations for the purpose of the Poisons and Pharmacy Act, 1908, and the Dangerous Drugs Act, 1920, was introduced by the Home Secretary in the House of Commons on Thursday, Feb. 15th. Clause 1 of the Bill amends Section 10 of the Dangerous Drugs Act, 1920, and gives power to a justice of the peace (or in Scotland a justice of the peace or the Sheriff) under certain circumstances to grant a warrant authorising any constable to enter, if need be by force, and search premises and persons found therein, if there is reasonable ground for suspecting that an offence against the Act has been committed in relation to drugs which may be found on such premises, or in the possession of such persons, and to seize and detain drugs and documents. Clause 2 amends Section 13 of the same Act and provides that each person guilty of an offence against the Act shall be liable on conviction or indictment in respect of each offence to a fine not exceeding £1000, or to penal servitude for a period not exceeding ten years, or to both such fine and penal servitude; or on summary conviction to a fine not exceeding £250, or to imprisonment with or without hard labour for a term not exceeding 12 months, or to both such fine and imprisonment. If a person attempts to commit an offence against the Act or solicits or incites another person to commit such an offence, he shall, without prejudice to any other liability, be liable on summary conviction to the same punishment and forfeiture as if he had committed an offence under the Act. Clause 3 amends Section 17 of the Pharmacy Act, 1868, as respects sales to medical practitioners, dentists, and veterinary surgeons.

The clause reads as follows: (1) So much of Section 17 of the Pharmacy Act, 1868 (which prescribes certain regulations to be observed in the sale of poisons), as requires an entry in the book to be kept under that section to be signed by the purchaser, shall not, if the conditions mentioned in this section are fulfilled, apply where the purchaser is a registered medical practitioner, in actual practice, and the purchase is made by him for the purposes of his profession. (2) The conditions to be fulfilled for the purposes of this section are as follows: (*a*) There must have been received by the seller before the sale an order in writing signed by the purchaser stating his name and address and the name and quantity of the article to be purchased. (*b*) The seller must be reasonably satisfied that the signature affixed to the order is in fact the signature of the person purporting to sign it, and that that person is a registered medical practitioner. (*c*) The article sold, if sent by post to the purchaser, must be sent by registered post. (*d*) The seller must enter in the book, in the column assigned to the signatures of purchasers, the words "signed order" followed by the date on which the order is executed, and must preserve the order for a period of two years from the date on which the final entry in the book is made. (3) This section applies to registered dentists and registered veterinary surgeons as it applies to registered medical practitioners.

HOUSE OF COMMONS.

THURSDAY, FEB. 15TH.

Pensions Nursing Staff and Sick Leave.

VISCOUNTESS ASTOR asked the Minister of Pensions whether all grades of female temporary staff employed by the Ministry, including the nursing staff, were liable to a deduction of 12*s.* per week from their salary during sick leave, even if they were ineligible for the receipt of the maximum amount of sickness benefit or for any benefit; and, if so, whether he would consider the possibility of making deductions for sick leave equivalent only to the amount actually received in benefit.—Major **TRYON**: The noble lady's statement is generally true so far as temporary women staffs in grades entitled to sick leave privileges are concerned. I am not prepared to modify the deduction in individual cases where for one reason or another the rate of benefit received is less than 12*s.*; and it is clear that any attempt to make sick leave regulations conform to the circumstances of individual cases would give rise to serious administrative difficulties.

Ex-Service Men in Lunatic Asylums.

Mr. **LANSBURY** asked the Minister of Pensions how many ex-Service men at present being treated in mental hospitals his department decided to hand over for maintenance as pauper cases to Poor-law authorities, and in how many cases had boards of guardians accepted chargeability for such cases.—Mr. **FREDERICK ROBERTS** asked the Minister of Pensions whether any scheme had been devised for the Ministry of Pensions to keep these men under their charge.—Major **TRYON** replied: The number of ex-Service men in asylums for whom the temporary responsibility of my department under the terms of the Royal Warrants has terminated in accordance with the express provisions of those Warrants is 750. A certain number of these cases are still under consideration by Appeal Tribunals and otherwise, and the figure I have given may still be somewhat reduced. I am not in a position to give information as to any refusal by a board of guardians to accept financial responsibility for these men. That is a matter which rests between the guardians and the asylum authorities. All cases of the class in question have received the most careful and sympathetic consideration, both by the medical officers of my department and by the Appeal Tribunals, with a view, if possible, to continuing their previous benefits consistently with the provisions of the Warrants; but as I have already stated, I am not prepared to accept the suggestion that my department should be permanently responsible for these or any other ex-Service men whose disabilities are not connected with their war service.

Disabled Men and Medical Treatment.

Mr. **FREDERICK ROBERTS** asked the Minister of Pensions whether his attention had been drawn to the fact that in numerous cases disabled men applying for treatment, when examined by the pensions medical referee and found unfit in consequence of his pensionable disability, were instructed to receive treatment from the panel instead of from the Ministry; whether he was aware that, when this decision was given, the men, though unfit for work, did not receive any treatment allowance but had to claim upon the National Health Insurance and in many cases, being out of benefit, were forced to appeal to charitable organisations or accept parish relief; and whether, in view of the fact that the Royal Warrant distinctly laid it down that men certified as requiring treatment would get the same at the expense of the Ministry and receive the appropriate allowances, he would see that the regulation was carried out.—Major **TRYON** replied: The Royal Warrant permits the grant of treatment allowances only when the requirements of a definite course of treatment approved by the Ministry are certified to be such as will prevent the man from providing for the support of himself and his family. If this condition is fulfilled, treatment allowances may be, and, in fact are, granted to men receiving treatment from their panel doctors. I may, perhaps, remind the hon. Member that my right hon. friend, the Prime Minister, has this week appointed a committee to examine the existing arrangements for the grant of assistance on account of sickness, unemployment, and destitution from public funds with a view to securing the fullest coördination of administrative and executive action.

Special Diet Allowances.

Mr. **BUCKLE** asked the Minister of Pensions whether, until recently, it was possible for men suffering from almost any medical complaint to receive special diet allowance; whether the regulations now only permitted of these being granted in cases of tuberculosis and diabetes mellitus; that no allowance was granted where the man was already in receipt of 100 per cent. pensions or treatment allowances, and that the allowance could not extend for a period of more than 13 weeks; and, if so, on what grounds it was decided to stop special diet allowances.—Major **TRYON** replied: The allowance for special diet is limited to men suffering from pulmonary tuberculosis and diabetes mellitus where the circumstances justify the concession. The period of 13 weeks referred to is simply the initial period and may be extended in any case on medical recommendation.

Mr. **JOHN DAVISON** asked the Minister of Pensions the average number of disabled men who received special diet or allowance for this purpose during the six months ended Dec. 31st, 1922, the number of such cases during the week ending Jan. 31st, 1923, and the percentage of such cases in which disablement was certified as tuberculosis.—Major **TRYON** replied: The average number of men who received special diet during the last six months of 1922 was about 165, of whom nearly 95 per cent. were cases of pulmonary tuberculosis. I have not got the figures for the week ending Jan. 31st last. In addition, during the last few months an average of about 2600 pensioners suffering from pulmonary tuberculosis have been in-patients in institutions and sanatoriums where they receive, at the cost of the Ministry, any special diet that may be medically recommended.

National Insurance Payments.

Mr. **SEXTON** asked the Minister of Labour, as representing the Ministry of Health, the amount annually paid from all sources under the National Health Insurance Act for any year since 1920, or including 1920, and the amount disbursed in sick benefit and administration, separately.—Sir W. **JOYNSON-HICKS** replied: For the year 1921, as regards England and Wales, the amounts are as follows:—

Amount paid from all sources under the National Health Insurance Acts	£36,356,000
Amount disbursed for benefits, including £7,200,000 sickness benefit	21,562,000
Amount disbursed in administration	4,827,000

Departmental Committee on Administrative Gaps.

Mr. **WEBB** asked the Prime Minister the membership and terms of reference of the Departmental Committee to inquire into the gaps between the provision made by the Ministries of Pensions, Health, and Labour, and the possibility of preventing hardship to sufferers from such gaps.—Sir **MONTAGUE BARLOW** replied: This Committee will be presided over by the Parliamentary Secretary to the Ministry of Labour (Major Boyd Carpenter) and will include representatives of the Ministry of Labour, Ministry of Health, Scottish Board of Health, and Ministry of Pensions. Its terms of reference are: "To examine the existing arrangements for the grant of assistance on account of sickness, unemployment, and destitution, from public funds and from the contributory schemes of health and unemployment insurance, with a view to securing the fullest coördination of administrative and executive action."

Closing of Military and Naval Hospitals.

Commander **BELLAIRS** asked the Under Secretary of State for War whether it had been possible to close any military hospitals, and, if so, where, as the result of the proposal for the exchange of patients between the fighting services; and if any other hospitals were under consideration with a view to closing.—Lieut.-Colonel **GUINNESS** replied: The military hospital at Chatham was closed in June last and all military sick of that garrison are now treated in the naval hospital there. The question is being kept under constant review with a view to treating the sick of the fighting services in one hospital at stations where it may be found practicable.

Commander BELLAIRS asked the First Lord of the Admiralty whether it had been found possible to close any naval hospitals, and, if so, where, as the result of the proposals for exchange of patients between the fighting services; if any other hospitals were under consideration with a view to closing; and whether the Yokohama naval hospital was still in existence.—Mr. EYRES-MONSELL replied: The only naval hospital which has been closed as the result of an exchange of patients between the fighting services is Gibraltar. At the present time it is not under consideration to close any other naval hospitals for a similar reason. Yokohama Naval Hospital is still in existence.

MONDAY, FEB. 19TH.

Carbon Monoxide Poisoning.

Major KELLEY asked the President of the Board of Trade whether he would coöperate with the Home Office in setting up an inquiry into the proportion of carbon monoxide and other deadly compounds now permitted in coal gas for domestic use; and whether he would introduce legislation to limit the proportion permitted of these compounds.—Viscount WOLMER (Parliamentary Secretary to the Board of Trade) replied: I would remind the hon. Member that a committee presided over by Sir William Pearce, then a Member of this House, considered this question less than two years ago. Their report was laid before the House, with the reference, Cmd. 1422. The recommendations of that committee are being carried out, and I am having a special examination made of the available statistics as to fatalities due to gas poisoning over a number of years.

Unhealthy Conditions at Smithfield Market.

Mr. TILLETT asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether he was aware that at Smithfield market it frequently happened that meat was piled on dirty pavements whilst awaiting loading, and that it was loaded in the carts and vans which frequently arrived in a filthy condition; and whether he would cause an inquiry to be made into the whole question of the handling and conveyance of meat at the public markets of London, in view of the great risk of disease and contamination to which it was exposed.—Colonel GIBBS replied: This matter is dealt with in the report of the Departmental Committee on Meat Inspection, published last year, and my right hon. friend proposes to make regulations giving effect to the recommendations of the committee on the subject.

An "All in" Method of Insurance.

Major BIRCHALL asked the Prime Minister whether, in the interest of economy and efficiency, he would consider the possibility of adopting an all-in method of insurance, so as to secure health, accident, hospital, unemployment, and additional old age benefits by one contribution.—Mr. BALDWIN (Chancellor of the Exchequer) replied: An inclusive scheme of this character would present enormous difficulties, administrative, political, and economic, and, apart from an appearance of simplicity, I am very doubtful whether it has much to commend it.

Inspection of Morphine Factories.

Lord ROBERT CECIL asked the Secretary of State for the Home Department what arrangements were in force for inspection of morphine factories in this country; and whether he was quite satisfied that adequate measures were taken to prevent abuses.—Mr. BRIDGEMAN replied: Morphine factories are subject to inspection by the Home Office inspectors under the Dangerous Drugs Act. Manufacturers are also required to keep detailed records and make periodical returns of their purchases of the raw material, their production of the drug, and their sales, and a licence has to be obtained for each consignment of the drugs which is exported from this country. We are doing all that is in our power to check the abuses of the drug traffic, but until full international coöperation has been secured it will be impossible to prevent them altogether.

Recruitment for the Indian Medical Service.

Sir JOHN HEWETT asked the Under Secretary of State for India what were the terms on which some 30 officers were recently recruited for the Indian Medical Service, and why these special terms had to be offered.—Earl WINTERTON replied: The terms offered in addition to the ordinary conditions of permanent service in the Indian Medical Service were a gratuity of £1000 and free return passages for officers who may wish to leave the Service at the end of five years. A similar gratuity is admissible to Royal Army Medical Corps officers after a somewhat longer period of service. The offer was necessitated by the serious shortage of European officers in the Service, resulting from a failure in the supply of candidates since the outbreak of war.

TUESDAY, FEB. 20TH.

Tuberculosis in Ex-Service Men Caused by Poison Gas.

Major PAGET asked the Minister of Pensions if, in view of so many men who were gassed during the war and who, since leaving the army had developed tuberculosis and were now unable to get pensions, he would cause an inquiry to be made into the whole subject.—Captain CRAIG (Lord of the Treasury) replied: It has always been the practice of the Ministry to give specially sympathetic consideration to cases of tuberculosis. Any evidence of gassing during service is invariably taken into account and full weight given to its possible bearing on the man's condition. My right hon. friend does not consider that any useful purpose would be served by an inquiry such as that suggested, but if my hon. and gallant friend has in mind any cases in which he considers justice has not been done, I shall be glad to inquire into them, if he will let me have particulars.

Agreement with Panel Practitioners.

Sir KINGSLEY WOOD asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether, in view of the expiration of the agreements at the end of this year with doctors on the panel lists, he was taking any steps to review the present scheme of medical benefit with a view to rendering it more efficient and economical.—Sir W. JOYNSON-HICKS replied: Yes, Sir, the existing arrangements for the medical treatment of insured persons are now being examined in detail by the Insurance Consultative Council of the Minister of Health.

The Spahlinger Treatment for Tuberculosis.

Captain WEDGWOOD BENN asked the Minister of Pensions whether his attention had been called to the Spahlinger treatment for tuberculosis; and whether it was intended to make this available for ex-Service patients.—Sir W. JOYNSON-HICKS replied: My right hon. friend, the Minister of Health, is informed that no supplies of M. Spahlinger's remedies are yet available in this country. When they become available it will be open to the medical officers responsible for the treatment of ex-Service men to utilise these remedies in the treatment of their patients if they consider it desirable.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Feb. 26th.

ODONTOLOGY: at 8 P.M.

Adjourned Discussion: Dental Sepsis as an Ætiological Factor in Disease of Other Organs.

Members of this Section are cordially invited to attend the Meeting of the *Section of Anæsthetics* announced for Friday, March 2nd.

Wednesday, Feb. 28th.

Social Evening.

Pasteur Centenary: This Social Evening will be devoted to celebrating the Centenary of the immortal Pasteur, and the President and Council hope that Fellows and their friends will make a special effort to honour the occasion by their presence.

The guests will be received by the President, Sir William Hale-White and Lady Hale-White at 8.30 P.M.

At 9 P.M. the President will deliver an Address on Pasteur in Relation to Medicine. This will be immediately followed by a short Lecture on Pasteur in Relation to Chemistry, by Prof. T. M. Lowry, C.B.E., F.R.S. (Professor of Physical Chemistry, Cambridge), and by a short illustrated Lecture on Pasteur as an Artist, by Dr. Gustave Monod.

The Library will be open and various objects of interest will be exhibited. Music, light refreshments, and smoking.

Thursday, March 1st.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

Specimens:

Prof. Henry Briggs: (1) Angioma of Vaginal Wall. (2) Section of Curettings.

Mr. Eardley Holland: Leio-myo-sarcoma of a Fibromyoma removed by Subtotal Hysterectomy.

Mr. A. C. Palmer: A large Secondary Mass of Leio-myo-sarcoma in the Peritoneum after Subtotal Hysterectomy for Multiple Fibroids, one of the latter being a Leio-myo-sarcoma.

Mr. J. Barris: Sarcoma of the Uterus (2 cases).

Mr. Gordon Luker: Chorion-epithelioma of the Uterus.

Paper:

Mr. Sidney Forsdike: The Treatment of Hæmorrhage at the Menopause by Radium, with a report upon 45 cases.

Friday, March 2nd.

LARYNGOLOGY: at 4.45 P.M. (Cases at 4 P.M.)

Dr. H. C. Cameron will show a series of cases with respiratory stridor due to meningeal hæmorrhage at birth.

Demonstration:

Dr. Jobson Horne: Tumours in the Inter-arytenoid Space of the Larynx.

Cases and Specimens will be shown by Dr. H. J. Banks-Davis, Mr. Musgrave Woodman, Mr. Walter Howarth, Mr. H. M. Wharry, Mr. E. D. D. Davis, and Sir James Dundas-Grant.

ANÆSTHETICS: at 8.30 P.M.

Paper:

Dr. W. J. McCardie: General Anæsthesia in Ordinary Dental Surgery.

ODONTOLOGY: Members of this Section are specially invited to attend the above meeting, and to take part in the discussion.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. 1.

Monday, Feb. 26th.—8.30 P.M., Discussion on The Various Methods of Treatment of Cancer of Tongue. Opened by Mr. James Berry, followed by Mr. Clayton-Greene, Mr. Wilfred Trotter, Mr. G. E. Gask, Mr. Gordon-Taylor, Mr. A. Edmunds, Mr. H. S. Clogg, Mr. Cecil Rowntree, and others.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

Thursday, March 1st.—5 P.M., Second Milroy Lecture:—Dr. W. G. Savage: Canned Foods in Relation to Health.

FELLOWSHIP OF MEDICINE POST-GRADUATE LECTURES, 1, Wimpole-street, W.

Monday, Feb. 26th.—5.30 P.M., Mr. Cecil Rowntree: Cancer of the Breast.

(At the Western General Infirmary, Marylebone-road, N.W.)

Tuesday, Feb. 27th.—5 P.M., Dr. B. Myers: Intoxication (Summer Diarrhœa, &c.).

Friday, March 2nd.—5 P.M., Dr. B. Myers: The Nervous Child as seen in General Practice.

UNIVERSITY OF LONDON ADVANCED LECTURES IN MEDICINE, Robert Barnes Hall, Royal Society of Medicine, 1, Wimpole-street, W.

(Course of Three Free Lectures.)

Wednesday, Feb. 28th.—5.30 P.M., Sir Archibald E. Garrod: General Review of Inborn Errors of Metabolism.

UNIVERSITY COLLEGE, Gower-street, W.C.

(Course of Three Public Lectures in the Physiology Theatre.)

Wednesday, Feb. 28th.—5 P.M., Mr. A. H. Drew: The Cultivation of Tissues in Vitro.

WEST END HOSPITAL FOR NERVOUS DISEASES.

The following Clinical Demonstrations will be held during the forthcoming Session in the Out-patient Department of the Hospital, 73, Welbeck-street, W. The Demonstrations are open to Practitioners and Medical Students without fee.

Monday, Feb. 26th.—1.30 P.M., Dr. Harry Campbell: Cerebellar Disease.

Thursday, March 1st.—1.30 P.M., Dr. Macnamara: Psychasthenia.

C. Worster-Drought, M.D., Dean.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

Monday, Feb. 26th.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.

Tuesday.—10.30 A.M., Dr. Paterson: Demonstration of Medical Cases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

Wednesday.—11 A.M., Mr. Simson: Gynæcological Demonstration. 12 noon, Dr. Burnford: Pathological Demonstration. 2.30 P.M., Dr. R. M. Bruce: Demonstration of Fever Cases.

Thursday, March 1st.—10 A.M., Dr. Grainger Stewart: Neurological Department. 12 noon, Mr. Simmonds: Demonstration of Fractures. 4 P.M., Dr. Mitchell Bruce: Age Relations of Diseases of the Heart.

Friday.—12 noon, Dr. Flett: Radiology. 2 P.M., Mr. Banks-Davis: Diseases of Nose, Throat and Ear. 3 P.M., Mr. Sinclair: Surgical Cases.

Saturday.—9 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10.30 A.M., Mr. Maingot: Surgical Pathology.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

Thursday, March 1st.—4.30 P.M., Mr. Macleod Yearsley: Demonstration of Aural Cases.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-Square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: Jan.–March, 1923.

Clinical Lectures and Demonstrations.

Monday, Feb. 26th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., X Ray Demonstration: Dr. Russell Reynolds.

Tuesday, Feb. 27th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Head Injuries: Mr. Armour.

Thursday, March 1st.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Lecture:—Pituitary Disease: Dr. Gordon Holmes.

Friday, March 2nd.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Labyrinthine Disease and Its Investigation: Mr. Sydney Scott.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

Neuro-Pathology.

Monday, Feb. 26th.—12 noon, Syphilis of the Nervous System: Dr. J. Godwin Greenfield.

N.B.—A Course of Lectures in the Anatomy and Physiology of the Nervous System will be given if there are sufficient entries for it.

The fee for the whole Course, including Anatomy and Physiology, is £12 12*s.*; but these Lectures may be taken separately for a fee of £4 4*s.* Course without Anatomy and Physiology Lectures will be £10 10*s.* Any part of the Course may be taken separately at a special fee. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.

C. M. Hinds Howell, Dean of Medical School.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, Marylebone, W.

Thursday, March 1st.—5.30 P.M., Dr. R. O. Moon: Heart Diseases and Occupations.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Thursday, March 1st.—4 P.M., Mr. Higgins: Rectal Surgery.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

Thursday, March 1st.—5 P.M., Dr. W. Griffith: The Bullous Eruptions.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

Tuesday, Feb. 27th.—4.15 P.M., Dr. C. H. Melland: Some Cases of Cardiac Irregularity.

Friday.—4.15 P.M., Dr. E. M. Brockbank: The Microscopical Examination of the Blood in the Diagnosis of Disease.

ST. MARY'S HOSPITALS, MANCHESTER. POST-GRADUATE LECTURE (Whitworth-street West Branch).

Friday, March 2nd.—4.30 P.M., Mr. J. Morley: Appendicitis in Children.

MANCHESTER BABIES' HOSPITAL, POST-GRADUATE LECTURES, Slade-lane, Levenshulme.

Saturday, March 3rd.—4 P.M., Miss Harriette Chick: Recent Experimental Work on Rickets and its Application to Infants.

The lecture by Dr. N. H. Parry, announced for Saturday, Feb. 24th, has been cancelled.

SALFORD ROYAL HOSPITAL. POST-GRADUATE LECTURE.

Thursday, March 1st.—4.30 P.M., Dr. Higgins: The Differentiation of the Normal from the Abnormal in the Radiology of the Bones.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

Wednesday, Feb. 28th.—4 P.M., Mr. E. R. Townley Clarkson: Notes on Venereal Clinics: Their Function and Organisation.

Appointments.

Chambers, E. R., F.R.C.S.Edin., D.O.M.S.Lond., M.R.C.S., L.R.C.P.Lond., has been appointed Ophthalmic Surgeon, Bristol Royal Infirmary.

Lewis, F., M.R.C.S., L.R.C.P., House Surgeon, Durham County Hospital.

Nelson, T. S., M.R.C.P. Lond., M.A., B.M., B.Ch. Oxf., Assistant Physician to the Brompton Hospital for Consumption and Diseases of the Chest.

Stallard, R. E. W., (Mrs.), M.D., B.S. Lond., Honorary Surgeon to the Herefordshire General Hospital.

Young, G., M.B., Ch.B.Glasg., Certifying Surgeon under the Factory and Workshop Acts for Cockermouth.

Medical Referees under the Workmen's Compensation Acts: Kilvert, J. E., M.R.C.S., L.R.C.P.Lond. (Circuit No. 19); Rotherham, F. H., M.B.Lond., L.S.A. (Circuit No. 17); Solly, E., M.B.Lond., F.R.C.S.Eng. (Circuit No. 15); and Whitelocke, R. H. A., M.D.Edin. (Circuit No. 36).

David Lewis Northern Hospital, Liverpool: Chamberlain, E. N., M.B., Ch.B. Liverp. (Senior), Cookson, C., Corlett, R. L., Hughes, H. T., Pridie, E. D., and Sykes, J. E., Resident Medical Officers.

Vacancies.

For further information refer to the advertisement columns.

Bath, Ministry of Pensions Hospital.—Jun. M.O. £350.

Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H. S. £175.

Birmingham General Hospital.—H.S., Obstet. H.S., and Res. Anæsth. Each £70.

Birmingham Orthopædic Centre.—Jun. M.O. £350.
Bolingbroke Hospital, Wandsworth Common, S.W.—Radiologist.
Bristol General Hospital.—H.P.'s and H.S.'s, &c. Each £125.
Burnley County Borough.—M.O. for Ven. Dis. £850.
Cardiff City.—Asst. M.O. £550.
Cardiff, Welsh National School of Medicine.—Lecturer in Forensic Medicine and Toxicology. £50.
Cheadle, Cheshire, Cheadle Royal.—Asst. M.O. £350.
Chester Royal Infirmary.—Hon. Asst. P.
Colchester, Essex County Hospital.—H.P. £200.
Derby, Nightingale Nursing Home.—Hon. Obstet. P.
Enfield, Middlesex, War Memorial Hospital.—Hon. Radiologist.
Evelina Hospital, Southwark, S.E.—S. to Out-patients (Hon.).
Exeter, Royal Devon and Exeter Hospital.—Sen. H.S. and Asst. H.S. £250 and £150 respectively.
Freemasons' Hospital and Nursing Home, 237, Fulham-road, S.W.—R.M.O. £250.
Hastings, East Sussex Hospital.—Hon. Asst. S.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S., H.P., and Asst. Cas. O. Each £50.
Industrial Orthopædic Society, Manor House Hospital, Golders Green, N.W.—Med. Referee.
Leeds Public Dispensary.—Jun. Res. M.O. £150.
Liverpool Maternity Hospital and Ladies' Charity.—Hon. Asst. S.
London Temperance Hospital, Hampstead-road, N.W.—H.P. £120.
Maidstone, West Kent General Hospital.—H.S. £220.
Manchester, Ancoats Hospital.—R.M.O. £200. Med. Reg. £100. H.S. £100.
Manchester, Baguley Sanatorium.—Third A.M.O. £300.
Manchester Northern Hospital for Women and Children.—Anæsthetist. Half guinea per hour. Also Hon. Dental S.
Metropolitan Ear, Nose, and Throat Hospital, 2, Fitzroy-square, W.—Sen. Clin. Asst.
Newcastle-upon-Tyne Hospital for Sick Children.—Sen. and Jun. R.M.O.'s. £170 and £140 respectively.
Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £150.
Nottingham Board of Guardians.—District M.O. A'so Public Vaccinator.
Oldham Union Poor-law Institution, Rochdale-road.—Res. Asst. M.O. £300.
Royal Free Hospital, Gray's Inn-road, W.C.—Second Ven. Dis. Asst. £100.
Royal Northern Hospital, Holloway-road, N.—M.O. to Out-patients. £150. H.P. and H.S. Each £100. Surgeon for Diseases of Ear, &c.
St. Andrew's Hospital, Dollis Hill, N.W.—Hon. Radiologist.
Seamen's Hospital Society, Greenwich, S.E.—H.S. and H.P. £150.
Sheffield, South Yorkshire Asylum.—M.O. £400.
Shrewsbury, Royal Salop Infirmary.—H.P. £160.
South Shields County Borough.—M.O. for Ven. Dis. £750.
Sunderland Royal Infirmary.—H.P. £160.
Wellcome Physiological Research Laboratories, Langley Court, Beckenham.—Bacteriologist.
Western Ophthalmic Hospital, Marylebone-road, N.W.—First and Second H.S.'s. £150 and £100 respectively.
West London Hospital, Hammersmith-road, W.—H.P. and Two H.S.'s. Each £100.
Westminster Hospital, Broad Sanctuary, S.W.—Surg. Reg. £50.
Weston-super-Mare Hospital.—H.S. £150.
Worthing Hospital.—Res. H.S. £150.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Leith (Edinburgh), Malling (Kent), Shefford (Bedford), Tuxford (Nottingham), Lostwithiel (Cornwall), Long Eaton (Derby), Foyers (Inverness).

Births, Marriages, and Deaths.

BIRTHS.

CAMPBELL.—On Feb. 8th, at Idmiston-road, W. Norwood, the wife of Donald Campbell, L.D.S. Edin., of a daughter.

CASEMENT.—On Jan. 24th, at Mount Abu, Rajputana, India, the wife of E. R. Casement, of a daughter.

MATTHEWS.—On Feb. 13th, at Onslow-square, the wife of Dr. Guy Matthews, of a son.

MCCOMBIE.—On Feb. 14th, at Courtfield-gardens, S.W., the wife of Dr. McCombie, of a daughter.

WOOLRICH.—On Feb. 10th, at "The Croft," Beechwood-road, Sanderstead, the wife of Dr. W. G. Woolrich of a daughter.

MARRIAGES.

MARTLAND—FITTON.—On Feb. 13th, at St. Mark's, Heyside, Oldham, Capt. Edward N. P. Martland, R.A.M.C., to Mildred, elder daughter of the late Walter Fitton, and of Mrs. Fitton, Birshaw House, Shaw, Lancashire.

VICARY—PEARCE.—On Feb. 13th, at St. Marylebone Parish Church, Surgeon Lieutenant-Commander Walter P. Vicary, R.N., to Nora, third daughter of Sir William and Lady Pearce of Park-crescent, Portland-place, W.

DEATHS.

BARRITT.—On Feb. 14th, at the French Hospital, Shaftesbury-avenue, Captain Wesley Barritt, O.B.E., (Mil. Div.), Dental Surgeon, of Harley-street, W., aged 52.

LONG.—On Feb. 16th, at the residence of Dr. Beatrice Hinkle, New York, U.S.A., of pneumonia following influenza, Dr. Constance Long, of 48, Gordon-square, W.C. 1.

YEOMAN.—On Feb. 11th (suddenly, of pneumonia), at Hornby Lodge, Prestwich, Stanley Yeoman, M.B., B.C. Camb., M.R.C.S. Eng., aged 57 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

AN OUTBREAK OF CHICKEN CHOLERA:

A BACTERIOLOGICAL AND HÆMATOLOGICAL STUDY.

BY A. KNYVETT GORDON, M.B. CAMB.,

MEDICAL SUPERINTENDENT OF THE VIROL PATHOLOGICAL RESEARCH LABORATORIES; PATHOLOGIST TO THE GREAT WESTERN RAILWAY FUND.

IN June, 1922, I was asked by Dr. H. A. Lake, of Beaminster, to investigate an outbreak of disease in a chicken farm in his district. The sequel presented some interesting features. The farm in question was devoted exclusively to the rearing of a fine strain of white leghorn fowls which had been bred on Mendelian lines. Previously healthy, the flock had just been visited by an outbreak of disease, the main feature of which was the suddenness of the onset and the fact that—so far as could be ascertained—the chickens mostly died within 24 hours with no symptoms except collapse; diarrhœa and catarrhal signs were both absent. Some dead chickens had been previously examined by a lay expert and stated to have suffered from coccidiosis, the diagnosis having apparently been made simply on the presence of white patches in the walls of the intestine. Later I was shown similar birds when I visited the farm; the white spots were obviously enlarged Peyer's patches.

In the first instance, however, I received a package containing six birds, all of which had been alive when despatched 24 hours previously from the farm. On arrival two were alive (A and B) and four dead (C, D, E, F). The living birds appeared healthy, but the dead ones were greatly emaciated. A and B were killed and all six birds submitted to a bacteriological and histological examination including a study of the heart's blood.

Macroscopical Examination.—All showed signs of septicæmia, slight in A and B and well-marked in the rest. The pleura and peritoneum were studded with petechial hæmorrhages and the liver and spleen were engorged and soft. The blood was fluid and "tarry," and the intestinal mucosa injected with a few capillary hæmorrhages in C, D, E, and F. No gross sign of coccidiosis was present, and films from the intestinal contents showed no coccidia in any stage. Cultures were taken with aseptic precautions and films prepared from the heart's blood and spleen of all the birds. Sections were made of the livers and spleens of A and F.

Microscopical Examination.—The livers showed dilatation of the interlobular veins, some biliary engorgement, and fatty degeneration of the hepatic cells, the changes being slight in A and well-marked in F. The spleens showed marked engorgement with cells which were found in films stained by the panoptic method to consist mainly of leucoblasts and cells of the lymphoidocyte type.

Bacteriology.—From the heart blood of A and B the bacillus of chicken cholera (Pasteurella) was grown in pure culture. The same organism was also present in cultures from the dead birds but contaminated with a long sporing bacillus, the nature of which was not fully investigated.

Hæmatology.—This was interesting. I may remark that in the normal fowl the red cells are nucleated and resemble something between the normoblast and megaloblast in the human subject. Polychromasia is absent. The normal leucocyte is of the leucoblast type—i.e., in man the ancestor of both granular (polymorphs) and non-granular cells (lymphocytes). This, incidentally, is what we should expect on the principle that the development of the individual is a recapitulation of that of the race.

In the dead birds the red cells were of three types: (*a*) the normal erythrocyte, (*b*) cells exactly resembling the human megaloblast, and (*c*) large polychromatic megaloblasts, some of which seemed to be intermediate stages between (*b*) and lymphoidocytes. In birds A and B a few megaloblasts were found on exhaustive search, but no polychromasia. The white cells showed total leucocytosis slight in A and B, well-marked in C, D, and E, and extreme in F. The cells were mainly of the normal "leucoblast" type, but in all typical lymphoidocytes (the ancestor of all blood cells, both red and white) were present. Of these, in A and B a few only were found on careful search, in F they numbered 25 per cent. The blood of all the dead birds also showed granular masses of protoplasm similar to those seen in advanced human leukæmia; they are probably dead leucoblasts in each case. All films were stained by the author's modification of Pappenheim's panoptic stain.

I then visited the farm with Dr. Lake. It was obvious that with the exception of one open field all the ground adjoining the huts in which the fowls were kept must have been by this time heavily charged with excreta of infected birds. It seemed impossible to devise any method of adequate disinfection thereof, so even if all the birds were slaughtered a recrudescence of infection in the new stock seemed likely to occur. Consequently, a vaccine was prepared from the strain of Pasteurella isolated from birds A and B and the whole colony of 700 birds was inoculated therewith, an initial dose of 1000 millions being followed a week later by double the quantity. The result was successful. With the exception of four birds, which died shortly after the first inoculation and were probably infected, all recovered and no further cases of disease occurred. As much time and research had been spent on the perfection of the strain, which was a valuable one, the result was regarded as satisfactory.

While vaccination with attenuated live cultures is well known as one of Pasteur's classical experiments, I have been unable to discover in the literature of the subject any similar case of the use of an autogenous dead vaccine in chicken cholera. As the disease appears to be fairly prevalent I suggest that this procedure may be of practical use to chicken farmers. To the hæmatologist the presence of lymphoidocytes in the blood of the infected birds affords an interesting study in comparative pathology. In the fowl—as in some reptiles—the lymphoidocyte is only one stage further back than the normal leucocyte, so one would expect this cell to be present in the same way as in man when under certain conditions—e.g., severe bacillary infection—leucoblasts appear in the circulation. I may here remark that in a study of the blood in very young tadpoles I have found lymphoidocytes present together with intermediate forms both between the nucleated red cells and the white cell of the blood of the fully developed frog. Here, as in birds, this is of the leucoblast type.

I must gratefully acknowledge the courtesy of the owner of the farm, Mr. C. A. C. Streatfield, who throughout the investigation gave me every facility, including detailed clinical notes of the epidemic.

THE BRITISH SCIENCE GUILD.

We have received from the Council of the British Science Guild an appeal for popular support contained in a booklet descriptive of the aims and work of the Guild. No technical qualifications are necessary for membership of this national organisation ; although the latter has been in existence since 1905, its development has been hindered by lack of adequate funds. Its aims are briefly : (1) To stimulate among all classes active coöperation in national progress by the effective alliance of creative science, constructive invention, and productive industry ; (2) to promote and extend throughout the United Kingdom and the Empire the use of accurate knowledge and scientific method in all industries, public affairs, and services ; (3) to foster and diffuse the gifts of science among the young generation, and develop interest and enthusiasm in their power as applied to human welfare.

Methods of the Guild.

The methods by which the Guild works towards these ends are as follows : (*a*) The establishment of a headquarters organisation in London with ample funds and self-supporting branches in the provinces and Dominions ; (*b*) provision of annual prizes, similar to the Nobel prizes, for scientific or medical discovery of practical value to humanity, or for new applications of science ; of annual prizes open to all schools, and of travelling bursaries to suitable students, throughout the Empire ; (*c*) to continue the appointment of special committees of experts to examine and report on developments felt to be urgent and ripe for realisation ; (*d*) compilation of up-to-date consultative registers of progress in scientific and technical research and of scientific and technically equipped men and women, for use in information bureaus in London, the provinces, and the Dominions ; (*e*) formation at headquarters of administrative committees to maintain touch with all legislative proposals of the Empire ; to popularise scientific and technical aspects of State and public enterprises ; (*f*) provincial and Dominion branches to coöperate in (*e*) ; to link up existing scientific and administrative organisations and to make it possible for local administrative and public problems to be examined and suitably tested first by experts ; (*g*) to initiate conferences with non-scientific and class organisations, professional or occupational ; to promote the development and application of inventions ; (*h*) to arrange for lectures, exhibitions, and scientific demonstrations at home and abroad, to conduct a monthly magazine on popular lines for intercommunication and propaganda, and to arrange for the production and display of instructive cinema films, &c.

Work of the Committees.

The work of the committees—on which many distinguished representatives of science, education, and industry have coöperated—has included consideration of the following subjects : Awards for medical discovery, British chemical industries, conservation of natural sources of energy, industrial research and the supply of trained scientific workers, national education, coördination of charitable effort, design and manufacture of microscopes, medical research, and many other medical questions, prevention of the pollution of rivers, technical optics, and manufacture of optical instruments, and veterinary research. Many very valuable reports have been prepared by the committees and forwarded to Government departments concerned with the matters dealt with in them. Recommendations of committees of the Guild have also been widely acted upon outside Government departments.

Exhibitions and Cataloguing.

In 1918 and 1919 the Guild organised highly successful exhibitions of British scientific products, under the patronage of His Majesty the King. Local branches of the Guild have been established at Cardiff, Portsmouth, Glasgow, Newport, Brighton, and Birmingham, and several other centres are ready to be associated with the Guild's activities. The Guild's catalogue of British scientific and technical books, published in October, 1921, has been most favourably received. It contains the titles and bibliographic particulars of 6400 books, classified under approximately 50 main headings and 500 sub-headings, together with an index of authors and a subject index.

Forthcoming Meeting.

The promotion of efficiency and economy in industry, commerce, and all Imperial affairs by the progressive use of science and scientific method will be the subject of a public meeting to be held at the Mansion House on Feb. 27th, at which the Lord Mayor of London (a vice-president of the Guild) will preside.

THE TRAINED RADIOGRAPHER.

The Society of Radiographers has recently issued a pamphlet[1] descriptive of its foundation and aims. The society was incorporated under the Companies Acts (1908–1917) on August 6th, 1920, with a view to giving a definite professional status to certificated non-medical assistants who work in X ray and electro-therapeutic departments. In order to put an end to the confusion with regard to the terms "radiographer" and "radiologist," it has now been generally agreed that the term "radiologist" shall be applied to members of the medical profession who undertake radiographic diagnosis and treatment by means of X rays and radium, while the term "radiographer" shall be applied to their trained non-medical assistants. The increasing complexity of X ray installations make it essential that assistants employed in their manipulation shall have undergone an adequate technical training and shall receive some official recognition of their responsibilities in view of the dangers attending the unskilful use of X rays. The society was formed to comprise those approved persons who are at present working at the subject, and to qualify new workers after due training and an exhaustive examination. Hospital authorities are reminded in this pamphlet that they may become liable to legal proceedings on the part of a patient who has suffered damage from unskilful application of X rays, and that an unskilled assistant may himself incur injury, and may claim damages as a result of such injury, while in the service of an institution. To avoid complications such as these a joint committee was formed consisting of representatives of the British Association for the advancement of Radiology and Physiotherapy, the Institution of Electrical Engineers, and of the practical radiographer-assistants themselves ; and as a result the Society of Radiographers was formed, as far as possible on the same principles as those of the Pharmaceutical Society. An examination of a definitely high standard is held twice in the year, the subjects of examination being : Elementary Physics and Chemistry, the Principles of Apparatus Construction and Technique, Radiography, Radiation Therapy, and Radiographic Anatomy ; successful candidates receive the Diploma of Member of the Society of Radiographers (M.S.R.). It is explicitly laid down in the constitution of the society that its members shall not undertake treatment in any shape or form except under the direction of a qualified medical practitioner. The society as now constituted numbers some 120 members ; Sir Archibald Reid is president, and the society is governed by a Council comprising members of the three bodies which formed the joint committee. It is hoped that hospitals will coöperate with the society by employing only duly qualified persons as assistants in the responsible positions in X ray departments. A bureau has been formed in connexion with the society for the purpose of supplying information both to radiographers seeking employment and to institutions which require the temporary or permanent services of trained radiographers. Communications on either of these subjects should be addressed to the secretary, Society of Radiographers, 12, Stratford-place, W. 1.

Being an Expansion of a Lecture delivered at a Special Meeting of the Royal Society of Medicine on Nov. 30th, 1922,

By Sir ALMROTH E. WRIGHT, M.D., F.R.S.

Part II.*

We are now in a position to examine in more detail the nature of epiphylactic response. Certain very simple reconnoitring experiments give us our bearings. The experiments in question consist in killing the leucocytes, in some cases before, in other cases after, implanting microbes into the blood and seeing how far this killing of leucocytes affects bacterial destruction. An illustrative experiment is subjoined. Here before the microbes were implanted, the blood was heated to a temperature of 46° C.–48° C., this being a temperature which kills the leucocytes and leaves the serum, and if not kept up unduly long, also the microbes unaffected.

Here graduated implantations of staphylococcus were made by the "wash and after-wash" method into a series of volumes of A. E. W.'s blood, these volumes being drawn up one after the other into a long-stemmed capillary tube.

—	Number of colonies which developed in vols.															Total in the last 12 vols.
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	
A (1)..	3	2	1	0	0	0	0	0	0	0	0	0	0	0	0	0
A (2)..	3	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
B (1)..	+	+	+	3	3	2	1	1	0	1	0	1	1	0	0	13
B (2)..	+	+	+	5	5	2	0	0	0	0	1	0	0	0	0	13

A = Unheated blood. B = Blood pre-heated to 48° C.
The sign + is employed to indicate that the colonies were too closely packed to allow of accurate enumeration.

It will be clear from this quite typical experiment that the killing of leucocytes makes a very profound difference. The pre-heating of the blood abolishes or nearly abolishes, in two several ways, the bactericidal power of the blood for staphylococci and streptococci. First, it puts an end to phagocytic action (in the case of my own blood that would apparently not count for much); and further (and this in all bloods counts for a great deal more) it abolishes also the power of epiphylactic response, the blood being then left with only such microbicidal powers as it possessed ab origine. With respect to the experiments in which the blood, after microbes have been implanted, is heated sufficiently to kill the leucocytes and not sufficiently to affect the serum or injure the implanted microbes, these experiments give, as you will expect to hear, results which are in absolute agreement with those obtained in implanting and explanting experiments. When we implant into a blood and then immediately apply a temperature of 46°–48° C. we obtain very much less growth than in an ante-heated blood. Appreciably more microbes are killed when we apply heat after the lapse of even a minute, and when, before heating, the implanted blood is allowed to lie upon the bench for an hour or so, the cultural results are practically the same as in a blood which is left unheated.

Experiments which show that when Epiphylactic Response is Evoked in the Blood the Bactericidal Power of the Serum is Increased.

Such experiments as those cited in which the blood is heated either before or after the implantation of microbes are, it must be remembered, only reconnoitring experiments. They do not make it absolutely certain that it is by the action of the leucocytes or almost exclusively by their action that staphylococci and streptococci are killed in the blood. And again, these heating experiments—and the same applies, of course, to all experiments made with the whole blood—tell us nothing except by way of indirect inference with regard to the manner in which the killing of the microbes is accomplished. To arrive at certain knowledge we must experiment with each of the elements of the blood separately.

We may advantageously begin by satisfying ourselves that epiphylactic response goes hand in hand with a development of increased bactericidal power in the serum. As I have already elsewhere[1] shown that this holds true of human blood vaccinated in vitro, I may profitably here cite experiments of a different kind—experiments in which vaccines of dead microbes are inoculated intravenously into animals and man, and experiments in which the sera are tested immediately and at different time-intervals after inoculation.

Experiments on Rabbits.

Here a vaccine of dead microbes was inoculated intravenously, samples of blood were withdrawn before and at intervals after inoculation, and then similar implantations of living staphylococci were by the wash and after-wash method made into a sequence of 10 c.mm. volumes of each serum. The figures in the table show the number of staphylococci which grew out into colonies in the different sequences of 10 c.mm. volumes—the numbers being in each case expressed in terms of microbes per c.cm. of serum.

Rabbit.	Microbes per c.cm. which grew out into colonies in sera of bloods drawn off before and after injection of vaccine.							Additional number of microbes killed by the serum after injection of vaccine.
	Before	1 min. after	15 min. after	30 min. after	1 hr. after	3 hrs. after	6 hrs. after

2. Inoculated as Rabbit 1	2200	1200	200	—	—	400	0	At least 2200 per c.cm.
3. Inoculated with 14,000 streptococcus pyogenes per c.cm. of blood ..	5000	500	0	—	0	—	0	At least 5000 per c.cm.

Staph. = Staphylococci.

Experiments on Man.

I. Here 250,000 dead streptococci—i.e., about 40 streptococci per c.cm.—were injected intravenously into A. E. W.'s blood, samples of blood were drawn off before and after the injection, and the bactericidal powers of the sera were tested by implanting by the wash and after-wash method graduated doses of living staphylococci into a sequence of equal volumes of serum, filled in each case into a long capillary tube.

---

* Part I. appeared in The Lancet of Feb. 24th.

[1] Comptes Rendus Académie des Sciences, October, 1918; The Lancet, March 29th, 1919, p. 489.

II. Here a dose of streptococcus vaccine equivalent to some 15 streptococci per c.cm. of circulating blood was inoculated intravenously into a patient suffering from a streptococcus infection. Samples of blood were taken immediately before, immediately after, and 24 hours after the injection. The sera were tested by implanting with living staphylococci by the "wash and after-wash" method in each case into a sequence of one 20 c.mm. and two 10 c.mm. volumes of serum.

—		Number of colonies which developed in—			
		Vol. 1.	Vol. 2.	Vol. 3.	In the 3 vols.	
Serum of blood before inoculation	(a)	11	1	1	13	13·5
	(b)	13	1	0	14	
Serum of blood immediately after inoculation	(a)	8	1	0	9	7
	(b)	5	0	0	5	
Serum 24 hours after	(a)	15	0	0	15	14
	(b)	13	0	0	13	

The difference of 6·5 colonies in 40 c.mm. of serum corresponds to a killing of 162 more staphylococci per c.cm. of serum.

III. Here a dose of vaccine corresponding to about 15 streptococci per c.cm. of circulating blood was inoculated intravenously into a patient suffering from a heavy cold, followed by a further intravenous injection of 10 streptococci per c.cm. of blood 24 hours after, when the cold was decidedly better.

The sera were tested by implanting 5 c.mm. of a staphylococcus suspension into 100 c.mm. volumes of serum.

August 23rd, 1922: Serum before inoc. furnishes 76 staph. colonies.

Serum immediately after inoc. furnishes 63 staph. colonies.

The difference of 13 colonies per 100 c.mm. corresponds to a killing of 130 more staphylococci per c.cm. of serum.

August 24th, 1922: The sera were here tested in the same way but, of course, with a different staphylococcus suspension.

Serum immediately before inoc. furnishes 40 colonies.
,, ,, after ,, ,, 30 ,,
,, 24 hours ,, ,, ,, 40 ,,

The difference of 10 colonies in 100 c.mm. corresponds to a killing of 100 more staphylococci per c.cm.

IV. Intravenous inoculation of a streptococcus vaccine into a normal man.

May 10th, 1922: 500,000 dead streptococci were inoculated, and the sera were tested by implanting a 20 c.mm. wash of a staphylococcus suspension in each case into three 20 c.mm. volumes of serum.

The volumes of serum immediately before inoculation furnished—
36, 38, and 30 colonies—average 35.
Those of serum after inoculation furnished—
27, 34, and 29 colonies—average 30.
Those of serum 20 hours after inoculation furnished—
23 and 28 colonies—average 25.

May 15th, 1922: 800,000 dead streptococci were inoculated. The sera were tested as before.

The volumes of serum immediately before inoculation furnished—
13, 16, and 9 colonies—average 13.
The volumes of serum after inoculation furnished—
7 and 8 colonies—average 7·5.
The volumes of serum 24 hours after inoculation furnished—
16 and 19 colonies—average 17·5.

Calculation shows that the blood immediately after the first inoculation killed 250 more staphylococci per c.cm., and 20 hours after 500 more per c.cm.; and that it killed immediately after the second inoculation 275 more per c.cm.

V. Intravenous inoculation of streptococcus vaccine into a normal man.

Dec. 29th, 1922: Sera from bloods drawn off before, 1½ hours after, and 5 hours after the inoculation of 160,000 dead staphylococci; 50 c.mm. volumes of each serum were implanted with 2·5 c.mm. of a 2700-fold dilution of a broth culture of staphylococcus.

Serum before inoculation furnished 47 colonies.
Serum 1½ hours after ,, ,, 21 ,,
Serum 5 hours after ,, ,, 42 ,,

Calculation here shows that the serum 1½ hours after inoculation kills 520 more staphylococci than before.

VI. Streptococcus endocarditis.

Sept. 16th, 1922: Sera from bloods drawn off before and immediately after an intravenous inoculation of 25,000 dead staphylococci. The technique employed and the staphylococcus suspensions employed were the same as in the last case.

Serum Before Inoculation.—Implanted with the more dilute suspension of staphylococcus furnishes 35 and 48 colonies (average 40·5); implanted with the more concentrated suspension 71 and 83 colonies (average 77).

Serum Immediately After Inoculation.—Implanted with the more dilute suspension furnishes 32 and 34 colonies (average 33); implanted with the more concentrated suspension 65 and 66 colonies (average 65½).

This, taking again the figures for the heavier implantation, works out as an increased killing of 11·5 per 50 c.mm. and 230 for 1 c.cm. of serum.

Experiments which Show that the Vaccination of Blood may Increase the Opsonic Power of Serum and also the Phagocytic Power of Blood.

Let me now go on to show that when epiphylactic response is evoked in the blood the opsonic power of the serum, and pari passu with this, if the phagocytic efficiency of the leucocytes is not reduced, the phagocytic power of the blood is increased.

Reference has already been made to the fact that the inoculation of the blood with bacterial vaccines increases the opsonic power of the serum. This development of opsonic power proceeds on quite similar lines to the development of bactericidal power. It manifests itself both in vitro and in vivo, and it begins practically immediately.

Experiments in which Vaccines were Inoculated Intravenously into Rabbits.

Rabbit 1.—Inoculated with 10 million of dead staphylococci (about 40,000 per c.cm.). Opsonic power of serum—before inoculation 1: 3 minutes after, 2·9; 1 hour after, 2·3; 1½ hours after, 3·0.

Rabbit 2.—Inoculated with 5 million of dead staphylococci (about 20,000 per c.cm.). Opsonic power of serum—before inoculation, 1; 3 minutes after, 1·2; 2¼ hours after, 1·3.

Experiments in which Vaccines were Inoculated into Human Blood in Vitro and in Vivo.

I. Intravenous inoculation of about 40 streptococci per c.cm. into A. E. W.'s blood. Blood 1 was drawn immediately before, blood 2 immediately after, and blood 3 15 minutes after inoculation. The opsonic power of the sera and the phagocytic efficiency of the leucocytes were then measured—the opsonic power by taking 1 volume of serum, 1 volume of the staphylococcus suspension, and 1 volume of washed leucocytes; the phagocytic efficiency by comparing the microbic intake obtained by using the same sera with the different leucocytes.

—	Staphylo-phago-cytic count.	Staphylo-opsonic index.	Average ingest of the 3 sera.	Phago-cytic effici-ency.
Washed corps. of blood 1—				
+ serum 1 + staph.	3·4	1	5	1
+ ,, 2 + ,,	5·5	1·6		
+ ,, 3 + ,,	6	1·8		
Washed corps. of blood 3—				
+ serum 1 + staph.	3·5	1	4	0·8
+ ,, 2 + ,,	3·9	1·1		
+ ,, 3 + ,,	4·8	1·4		

I want to draw attention here to three points: To the fact that the opsonic index of the blood goes up instantly; to the fact that the phagocytic efficiency of the leucocytes goes down; and to the fact that the effect of the increased opsonic power is in this case partially masked by the decreased leucocytic efficiency. This comes out when we regard serum 3, and note that it gives with the corpuscles of blood 1 an average ingest of 6, and with the corpuscles of blood 3 an ingest of 4·8 only.

We shall presently see that the changes which occur in the blood in acute streptococcic infections follow this pattern except only in the respect that we have there usually a smaller rise in the opsonic index and a much profounder fall in the leucocytic efficiency.

In the next experiment (II.) it will be seen there is: 1. A notable increase of strepto-phagocytic power obtained with both varieties of vaccine. 2. Further, in each case when a certain dose is exceeded the phagocytic power begins again to decline. Other results show that this decline is probably due to the increased opsonic power of the serum being now counterbalanced by a poisoning of the leucocytes. 3. In this particular case a greater rise in the strepto-phagocytic power is obtained with the homologous vaccine. This might, of course, be due to the homologous character of the vaccine, but it might also be due to the dose of streptococcus having been here more fortunately chosen, either from the point of view of its evoking a better opsonic response, or from the point of view of its being less toxic to leucocytes.

The same probably holds true of all the following experiments. In connexion with the sixth experiment of the series, it will, on comparing the phagocytic indices with the opsonic indices—i.e., on comparing the amount of phagocytosis obtained with the leucocytes of the vaccinated blood with that obtained with the leucocytes of the unvaccinated blood—be seen that increase in the opsonic power of the serum is to a large extent masked by the poisoning or exhaustion of the leucocytes.

II. Here, with a view to finding out what would be the better kind and optimum quantum of vaccine to add to a prospective donor's blood for the purposes of immunotransfusion graduated additions of typhoid and streptococcus vaccines were made to his defibrinated blood in vitro. The samples of blood were incubated with the vaccine for one hour in vitro, and were then tested for phagocytic power by adding one volume of streptococcus suspension to two volumes of defibrinated blood.

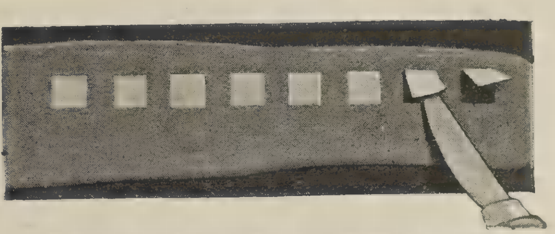
It will be seen that here in vitro, as in experiment I. in vivo, opsonic substances are delivered into the blood immediately—that is to say, they are furnished within the time that it takes to separate the serum from the corpuscles.

DERIVATION OF BACTERICIDAL AND OPSONIC SUBSTANCES FROM THE LEUCOCYTES.

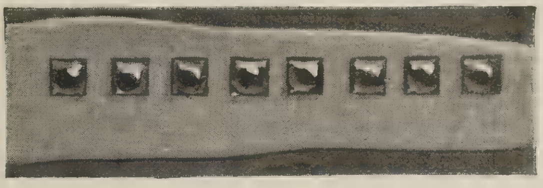
The leucocytes provide the bactericidal and the opsonic substances that appear in the serum when epiphylactic response is evoked in the blood. To make sure of this we must first isolate the leucocytes from the other elements of the blood, must then make graduated additions of vaccines to serum (or other menstruum), bring this into contact with the leucocytes, and then test its opsonic and bactericidal power. These requirements—and, of course, only the first presents any technical problem—are, as a matter of fact, easily satisfied. The leucocytes can be obtained entirely separate, for they will, if provided with facilities for doing so, emigrate from the blood. All they require is congenial warmth, a meshwork of fibrin to travel along, and a firm surface—such, for example, as the glass floor of an "emigration cell" or the walls of a capillary pipette—to collect upon.

FIG. 4.—A.



Method of making paraffin-framed emigration cells.

B.



Blood imposed on emigration cells.

Where emigration cells, such as are shown in Fig. 4 A are employed, these are, as in Fig. 4 B, filled brim full with blood taken direct from the finger.[2] After incubation in a moist chamber for one-half to three-quarters of an hour the clots are washed off with physiological salt solution. Where capillary pipettes are employed, the blood from the finger is drawn up into the stems, these are sealed up at the point, the barrel is then half filled with physiological salt solution, and then the blood is incubated for from half to three-quarters of an hour. After this a collapsed teat is fitted to the pipette, the tip of the stem is broken across, and the clot is slowly drawn up into the barrel and is then evacuated through the butt end along with the salt solution.

---

[2] Wright and Colebrook: Technique of the Teat and Capillary Glass Tube, Constable, 1921.

An emigration cell whose floor is coated with emigrated leucocytes may conveniently be called a *carpeted cell*, and a capillary tube similarly coated may be called a *lined tube*—the terms *uncarpeted* and *unlined* would then serve to denote control cells and capillary tubes with blank floors and walls.

The following experiments were carried out:—

I. Carpeted and uncarpeted emigration cells. A. E. W.'s leucocytes and serum. Here a 70-, a 300-, and a 600-fold dilution were made from a broth culture of staphylococcus. Of the first 5 c.mm. were implanted into 100 c.mm. of serum, and of the second and third 2·5 c.mm. into 50 c.mm. In each case half of the implanted serum was imposed on a carpeted and half on an uncarpeted cell. The two portions of serum were then, after a fixed interval, during which they were kept in a moist chamber on the bench, aspirated into fine capillary pipettes. These pipettes were then incubated for 24 hours, and the colonies which developed were counted.

(1) Serum with the heaviest implantation (which works out as 2200 staphylococci per c.cm.).

	Colonies.
25 c.mm. placed on an uncarpeted cell and immediately re-aspirated furnished	52 56
25 c.mm. placed on a carpeted cell and re-aspirated after 45 mins. furnished	26 15

(2) Serum with the intermediate implantation (which works out as 520 staphylococci per c.cm.).

	Colonies.
25 c.mm. placed on an uncarpeted cell and re-aspirated after 45 mins. furnished	13
25 c.mm. placed on a carpeted cell and re-aspirated after 45 mins. furnished	7

(3) Serum with the lightest implantation (which works out as 160 staphylococci per c.cm.).

	Colonies.
25 c.mm. placed on an uncarpeted cell and re-aspirated after 45 mins. furnished	4
25 c.mm. placed on a carpeted cell and re-aspirated after 45 mins. furnished	2

(4) A supplementary volume of serum with the same implantation as in (2).

	Colonies.
25 c.mm. imposed on an uncarpeted cell and re-aspirated after 45 mins. furnished	14
25 c.mm. imposed on the carpeted cell employed in (1) and re-aspirated after 45 mins. furnished	2

II. Carpeted and uncarpeted emigration cells. I. F.'s leucocytes and serum. Same technique.

Serum implanted with circ. 4800 staphylococci per c.cm. imposed on an *uncarpeted* cell and aspirated after 5 mins. furnished innumerable colonies.

Serum implanted with circ. 4800 staphylococci per c.cm. imposed on a *carpeted* cell and aspirated after 5 mins. furnished 79 colonies.

Serum implanted with circ. 1200 staphylococci per c.cm. imposed on an *uncarpeted* cell for 5 mins. furnished 30 colonies.

Serum implanted with circ. 1200 staphylococci per c.cm. imposed on a *carpeted* cell for 5 mins. furnished 14 colonies.

Serum implanted with circ. 520 staphylococci per c.cm. imposed on an *uncarpeted* cell for 5 mins. furnished 13 colonies.

Serum implanted with circ. 520 staphylococci per c.cm. imposed on a *carpeted* cell for 5 mins. furnished 2 colonies.

The possibility that the diminution in the number of microbes in the serum which had been imposed upon carpeted cells might be due to a percentage of the microbes sticking to the leucocytes is negatived by considering the effect of implanting in duplicate into broth progressive dilutions of a staphylococcus culture, and explanting the one series of volumes directly, and the other after imposition upon carpeted cells. An experiment of this kind gave the following result:—

Series of volumes of broth explanted directly on to agar gave 33, 14, 7, 5, and 4 colonies—in all 63 colonies.

A similar series explanted on agar after imposition on a carpeted cell gave 33, 20, 10, 2, and 1 colony—in all 66 colonies.

III. Carpeted and uncarpeted emigration cells, and also lined and unlined capillary pipettes. A. E. W.'s leucocytes and 30 c.mm. volumes of serum. A 120-, a 240-, a 480-, and a 960-fold dilution were made of a broth culture of staphylococcus. 2·5 c.mm. volumes of the last two dilutions were implanted into 50 c.mm. volumes of broth which were then aspirated into very fine capillary tubes. The two heavier implanted volumes furnished 55 and 54 colonies; (a similarly implanted volume of serum furnished 47). The two more lightly implanted volumes of broth furnished 25 and 27 colonies.

A series of 30 c.mm. volumes of serum were now implanted with 2·5 c.mm. of the different staphylococcus suspensions; were then imposed in each case for 30 minutes on carpeted emigration cells, and then drawn up into capillary tubes and incubated.

Vol. 1 implanted from the 120-fold dilution of staph. (i.e., with about 220 staph.) furnished	106	
Vol. 2 implanted from the 240-fold dilution of staph. (i.e., with about 110 staph.) furnished	25	
Vol. 3 implanted from the 480-fold dilution of staph. (i.e., with about 55 staph.) furnished..	29	28
Vol. 4 implanted from the 480-fold dilution of staph. (i.e., with about 55 staph.) furnished..	27	
Vol. 5 implanted from the 960-fold dilution of staph. (i.e., with about 28 staph.) furnished..	22	19
Vol. 6 implanted from the 960-fold dilution of staph. (i.e., with about 28 staph.) furnished..	16	

Calculation shows that here with an implantation of about 7500 staphylococci per c.cm. we have a killing of 50 per cent., with an implant of about 3600 a killing of 77 per cent., with an implant of 1800 a killing of 50 per cent., and with an implant of 900 a killing of only 27 per cent.

Supplementary Experiment.—Three 50 c.mm. volumes of serum, implanted respectively with 2·5 c.mm. of the 120-, 240-, and 480-fold dilution of the staphylococcus culture, were drawn up into lined capillary tubes. All these volumes remained sterile. This, if we take the figures for the heaviest implantation, works out as equivalent to the killing of 7200 staphylococci per c.cm. by the leucocytes obtained from 1 c.cm. of blood.

IV. Lined and unlined capillary pipettes. A. E. W.'s leucocytes and 40 c.mm. volumes of his serum. A 150-, a 300-, a 600-, a 1200, a 2400-, and a 4800-fold dilution were made of a staphylococcus broth culture.

2·5 c.mm. of the 4800-fold dilution gave in serum in *unlined* tubes 17 and 18 colonies.

2·5 c.mm. of the 2400-fold dilution gave in serum in *lined* tubes 15 and 17 colonies. In *unlined* tubes in serum 27 and 31 colonies and in an *unlined* tube in broth 31 colonies.

2·5 c.mm. of the 1200-fold dilution gave in serum in *lined* tubes 19 and 15 colonies, as compared with a calculated number of 60 for serum in an *unlined* tube.

2·5 c.mm. of the 600-fold dilution gave in serum in a *lined* tube 21 colonies, as compared with a calculated number of 120 for serum in an *unlined* tube.

2·5 c.mm. of the 300-fold dilution gave in serum in a *lined* tube 15 colonies, as compared with a calculated number of 240 for serum in an *unlined* tube.

2·5 c.mm. of a 150-fold dilution gave in serum in a *lined* tube 10 colonies, as compared with a calculated number of 480 for serum in an *unlined* tube.

In the case of the lined tubes the colonies that grew were in each case confined to the very narrow distal end of the capillary stem where the lining of leucocytes was probably deficient. Taking the figures for the most heavily implanted serum as they stand they testify to a killing of 63 per cent. with an implantation of 750 staphylococci per c.cm., a killing of 72 per cent. with an implant of 1500 per c.cm., a killing of 82·5 per cent. with an implant of 3000 per c.cm., a killing of 94 per cent. with an implant of 6000 per c.cm., and a killing of 98 per cent. with an implant of 12,000 per c.cm.

V. Lined and unlined capillary pipettes. A. E. W.'s leucocytes and 50 c.mm. volumes of his serum. A 30-, a 150-, a 300-, a 600-, and a 2400-fold dilution were made of a broth culture of staphylococcus.

2·5 c.mm. of the 2400-fold dilution gave in serum in a *lined* tube 0 colonies, in *unlined* tubes 6 and 10 colonies.

2·5 c.mm. of the 600-fold dilution gave in serum in a *lined* tube 6 colonies, as compared with 27 in an *unlined* tube.

2·5 c.mm. of the 300-fold dilution gave in serum in a *lined* tube 7 colonies, as compared with a calculated number of 54 for serum in an *unlined* tube.

2·5 c.mm. of the 150-fold dilution gave in serum in a *lined* tube 0 colonies, as against a calculated number of 108 for serum in an *unlined* tube.

2·5 c.mm. of the 30-fold dilution gave in serum in a *lined* tube 100 colonies, as compared with a calculated number of 500 for serum in an *unlined* tube.

Here again the colonies (except in the heaviest implanted serum where they were distributed over the whole length) were all confined to the distal extremity of the pipette.

Leaving this out of consideration and taking the figures as they stand calculation shows that with an implantation of 10,000 staphylococci per c.cm., 80 per cent. were killed; with an implant of 2000, 100 per cent.; with an implant of 1000, 87 per cent.; and with an implant of 560, 78 per cent.

We thus see that the laws governing epiphylactic response are the same for the leucocytes and serum as for the whole blood. Instead of obtaining with increasing implantations progressively less efficient killing (as we inevitably should if the bactericidal power were not enhanced by epiphylactic response) we obtain with increasing implantations (up to a certain limit) more and more effective killing.

I have now come to the end of what I have to say about the modus operandi of vaccines.

(To be concluded.)

THE TREATMENT OF MENORRHAGIA BY RADIUM.

By G. BLACKER, M.D., F.R.C.P. Lond.,
F.R.C.S. Eng.,
OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

Hæmorrhage from the uterus has now been treated by the intra-uterine application of radium in a sufficient number of cases to enable us to form a judgment as to the class of case for which it is suitable and the results which may be obtained. Radium can be used for the treatment of menorrhagia in three conditions—viz., cases in which the bleeding is associated with the menopause, cases in which it is due to the presence of small fibromyomata in the uterus, and cases in which it occurs in young women who present no signs of general or pelvic disease. Excessive hæmorrhage at the menopause is not uncommon and the loss may be so marked as to give rise to a high degree of anæmia. In the great majority of these cases the bleeding ceases spontaneously sooner or later, and no special treatment is called for, but in other cases the loss of blood is so great that it is necessary to take steps to arrest it. In this variety medicinal remedies have very little effect, and in the worst cases such measures as plugging the vagina or the cavity of the uterus, temporarily closing the cervical canal with sutures, or even hysterectomy, may have to be resorted to to arrest the bleeding. All these cases can be safely and efficiently treated by the intra-uterine application of radium, and this should always be employed in preference to any of the other measures when radium is available.

Problem of Excessive Hæmorrhage at the Menopause.

Whether we regard this excessive hæmorrhage at the menopause as due to some disturbance of the secretions of the internal glands, or to premature senility of the uterus resulting in an excess of fibrous tissue in its walls, the so-called fibrotic uterus of some writers, radium is equally applicable and certain in its results. It is a possible but unproven hypothesis that women who lose severely at the climacteric are the possessors of unduly fibrotic uteri which have undergone early and excessive senile changes, and that the presence of such an excess of fibrous tissue is the explanation of the fact that without any apparent cause some women bleed excessively at this period of life, while other women pass through the change without any disturbance in the regularity of or in the amount of blood lost at their periods. It may well be that women vary in the proportion of fibrous tissue present in their uteri at the menopause just as different individuals vary in the amount of fibrous tissue in the walls of their arteries at the same ages. Such a hypothesis would explain the failure of drugs to arrest the bleeding in these cases, at any rate those drugs which depend for their action on the setting up of uterine contractions.

Limitations of Uses of Radium.

While radium is especially useful in the treatment of excessive hæmorrhage at the menopause, it may also be employed for the arrest of hæmorrhage due to the presence of small fibromyomata in the uterus, or that occurring in young women without any apparent cause. Its use in fibromyomata of the uterus should be strictly limited to small tumours not larger than the uterus at the fifth month of pregnancy; not undergoing any form of degeneration; not complicated by any accompanying disease of the appendages; not causing pressure or other symptoms referable to their size; and not projecting markedly into the interior of the uterus. Within these strict limitations radium gives good results in arresting the bleeding and in ultimately causing shrinkage of the tumours. It should not be employed when the cavity of the uterus is much distorted, and it is wiser not to use it in submucous tumours for fear of injury resulting to the capsule of the tumour which might be followed by infection and sloughing of the growth. Although it is quite possible to bring about arrest of hæmorrhage and shrinkage of the fibromyoma when it is larger than a five months pregnant uterus, yet tumours of this size are best dealt with by operation and are unsuitable for radium treatment.

From time to time severe hæmorrhage occurs from the uterus in young women who are not the subjects of any general or pelvic disease, and whose age excludes the possibility of a premature menopause being a causative factor in the bleeding. In these cases it is common to obtain a history that curettage has been performed unsuccessfully on one or more occasions and that drug treatment has failed. By the intra-uterine application of suitable doses of radium it is possible to produce either complete or temporary amenorrhœa, and if the hæmorrhage returns the procedure can be easily and safely repeated.

Technique of Intra-uterine Application of Radium.

The technique of the intra-uterine application of radium is quite simple. The patient is prepared as for a curettage; under the anæsthetic a careful bimanual examination is made, particular attention being paid to the detection of any disease of the appendages. The cervix is dilated and an exploratory curettage is carried out, the scrapings being carefully preserved for microscopic examination. The interior of the uterus is douched out with hot lotion at a temperature of 118–120° F., and swabbed out with iodine or adrenalin if the bleeding is at all severe. The tube of radium, adequately screened, is introduced into the uterus up to the fundus; it is then withdrawn half an inch and the cervical canal plugged with ribbon gauze to prevent the tube slipping down into the cervix. The vagina is also lightly plugged with gauze. For convenience of withdrawal the ribbon gauze should have a piece of thread attached to it. At the end of the period of treatment the vaginal plug is removed, the cervical plug withdrawn by its thread, and finally the radium tube extracted by the piece of silk or silkworm gut attached to its carrier.

If the cervix has been adequately dilated up to the size of a No. 14 Hegar dilator no difficulty is, as a rule, experienced in withdrawing the tube; if however, any difficulty does occur it can be readily overcome by gentle continuous traction. In some patients the presence of the tube in utero produces marked sickness which persists until it has been removed, and in other women an attack of vomiting occurs at the time the tube is extracted through the cervix. The patient should be kept in bed for four to five days. In the case of a large uterus it may be necessary to use two tubes arranged tandem fashion in the same piece of rubber tubing.

The screen for an intra-uterine application should be such as to cut off all the beta and softer gamma rays so as to allow only the hard penetrating gamma rays to pass and act on the tissues. In the cases recorded in this paper the screens used were composed of 2 mm. of lead and 3 mm. of rubber for radium emanation tubes, and 1 mm. platinum and 2 mm. rubber for tubes containing radium element. Other screens of an equivalent density of gold, aluminium or brass may also be employed. The secondary rays, which are formed in the lead or platinum screen (rays of Sagnac), are effectively filtered off by the use of the 2–3 mm. thick rubber covering. It is desirable in treating cases of the same kind to use similar screens so that accurate comparisons of the results may be attained. One of the objections to the use of radium is that it requires an anæsthetic, but in reality this is an advantage, inasmuch as it allows of a thorough pelvic examination and an exploratory curettage being carried out, important factors in safeguarding the patient from the employment of the method in unsuitable conditions, and in avoiding the possibility of overlooking malignant disease.

Dosage.

The determination of the proper dosage is one of the difficulties in radium treatment. The average dose required in the treatment of hæmorrhage at the menopause may be said to be from 2000–2400 mg. or millicurie hours. In cases of fibromyomata of the uterus such a dose may have to be repeated on one or more occasions, and in the case of young women in whom it is desired to produce only partial or temporary amenorrhœa the amount used should be smaller, or, if the same, should be applied for a shorter period of time. Different patients, especially young women, appear to react to the same dose in very varying degrees, that is, exhibit different degrees of so-called "radio-sensibility," and it is therefore not always easy to determine the exact dose which will bring about a complete arrest of the periods, temporary arrest for varying periods of time, or only a diminution in the amount of blood lost. With increasing experience, however, we shall be better able to determine the exact dose required to bring about any desired effect. It is still a matter of difference of opinion whether the best results are obtained by the use of large doses for a short period of time or of smaller doses employed for a longer period of time, or repeated on one or more occasions. It is important to avoid any skin reaction, and at the same time it must be remembered that the age of the uterus does not always correspond to the age of the patient, and patients of similar ages may react very differently to the same dose of radium.

The terms "milligramme hours," and "millicurie hours" have been introduced by Dawson Turner to indicate the duration of the exposure. In these terms the dose is expressed by multiplying the number of milligrammes of radium element, or the numbers of millicuries of radium emanation used, by the time in hours of the exposure. While this method is not strictly accurate it provides a fair estimate of the effective dose employed, if at the same time the nature of the screens and the distance from the surface of the skin when the application is made externally are also given. The activity of a millicurie of radium emanation in gamma rays corresponds to the gamma ray activity of a milligramme of radium element.

In using radium emanations due allowance must be made for the gradual decay of the emanation, amounting, roughly, to three-quarters of 1 per cent. per hour. For clinical purposes it is sufficiently accurate to assume that 100 mg. applied for one hour or a dose of 100 mg. hours produces the same biologic effect as 50 mg. applied for two hours. Radium should never be introduced into the uterus in any case in which there are signs of inflammation of any part of the genital tract, and great care must be taken to exclude disease of the uterine appendages. For this reason a careful bimanual examination of the pelvis should be practised before the tube is introduced, and the interior of the uterus explored so as to exclude with certainty the possibility of any malignant disease.

Immediate Results.

It is best, whenever possible, to carry out the treatment at a time when the patient is not actually bleeding. The intra-uterine application of radium with proper technique in carefully selected cases may be said to be free from any danger. If it is used in cases of chronic pelvic peritonitis it may set up an acute attack, but the same result may follow any other pelvic procedure in such a case. The method does not, as a rule, give rise to any marked pain; some patients complain of general discomfort in the lower abdomen, and in others, after the sickness due to the anæsthetic has passed off, nausea may be complained of or vomiting may even persist until the tube has been removed. No rise of temperature occurs in an uncomplicated case, such as so often follows the use of radium in carcinoma of the uterus.

In a certain number of the cases complete amenorrhœa follows the treatment immediately, in others one or two often excessive losses occur before the cessation of the periods is brought about. This is more likely to be the case in young women or in those with fibromyomata of the uterus rather than in women at the menopause. In a few cases troublesome leucorrhœa or a slightly blood-stained discharge lasts for some four to six weeks, rarely for some months. It appears to result from the local destructive action of the radium on the endometrium, and is more likely to follow the use of large doses.

If the treatment brings about the complete cessation of the periods the minor symptoms of the menopause, such as flushings, usually follow. In cases in which the periods return after an interval it is not uncommon to find that the flushings have ceased simultaneously, and the administration of a second dose, if followed by amenorrhœa, will again cause the onset of these vaso-motor disturbances.

The excessive bleeding which not infrequently immediately follows the radium treatment has been ascribed to the liberation of hormones brought about by the destruction of Graafian follicles in the ovaries by the radium. In the majority of patients the cessation of the periods is followed by an improvement in the general health. Occasionally severe nervous symptoms may ensue on the menopause; thus, one of my patients, who before treatment suffered from extreme attacks of depression at the periods, which were excessive, has since their cessation developed severe melancholia and religious mania. In this case a dose of 2700 millicurie hours internally and one of 1320 millicurie hours externally brought about an arrest of the bleeding after four periods. In three cases radium burns with vesication and superficial ulceration followed the external application of large doses of radium applied over the ovarian regions. In these cases the doses used were 540, 1000, and 1100 millicurie hours, the emanation being screened with 2 mm. of lead, 3 mm. of rubber, and three thicknesses of lint. It has been calculated that the uterus will stand a dose three times greater than that required to produce a skin reaction, and in applying radium over the ovarian region it is most important to follow the technique suggested by Simpson and by means of suitable pads to distribute the radium used over a plane surface of sufficient size, and to place it at a sufficient distance from the skin to obviate any risk of causing injury to the superficial tissues.

Is Damage Brought About by Radium Treatment?

It has been suggested that the damage done by so powerful an agent as radium to the tissues of the uterus might cause in after years the production of a carcinoma of the body of the uterus. It is true that a few cases of carcinoma have been described as occurring after the use of radium, but there is no evidence to show that the radium application played any part in their causation. Leda J. Stacy has described three cases among 1013 cases treated at the Mayo Clinic by radium for benign conditions in the pelvis. In one case a patient, 55 years of age, who six and a half years previously had been operated upon for prolapse of the uterus, was treated in March, 1920, with a dose of 600 mg. hours of radium for hæmorrhage from the uterus. In January, 1921, she complained of an odourless bloody discharge, and received a further dose of 700 mg. hours and X ray treatment to the abdomen. In January, 1922, she had abdominal pain and discharge; hysterectomy revealed a carcinoma of the fundus uteri. In a second case a patient was given an intra-uterine application of radium of 500 mg. hours for fibromyomata of the uterus; this was followed by amenorrhœa for two years. At the end of two and a half years she developed a blood-stained discharge and abdominal pain, and the uterus when removed showed a carcinoma of the body.

Jacobs has described the case of a woman of 47 with small fibromyomata of the uterus, who was treated for profuse menorrhagia in October, 1919, with 148 mg., applied for 48 hours, above the pubes and in the cervix, and this treatment appears to have been repeated every three weeks for four months. In June, 1920, she had had no periods for three months. In July she developed severe hæmorrhage and an offensive discharge, masses of growth came away through the cervix, and she died in September. In this case the patient would appear to have received the enormous dose of 33,600 mg. hours of radium; there is, however, no record of any intra-uterine exploration, and the tube was placed in the cervical canal, not in the uterus. The history suggests the development of a sarcoma rather than a carcinoma. If any large series of cases of menorrhagia are treated with radium, a proportion of them is certain to develop cancer of the body of the uterus, but it would require a very large number of observations to establish any definite relation between the use of radium and the development of malignant disease.

Series of Cases Treated Personally.

During the period July, 1916, to the end of June, 1922, I have had under my care 77 patients treated by the intra-uterine application of radium emanation or radium element. Of these nine unfortunately have been lost sight of. Of the remaining 68, 34 were treated for profuse hæmorrhage at the menopause, 23 for hæmorrhage associated with fibromyomata of the uterus, and 11 for menorrhagia unaccompanied by any general or pelvic disease. Of the 34 cases at the menopause the ages varied from 40 to 52 years. All of them were suffering from severe hæmorrhage calling for treatment, 10 of them had been curetted unsuccessfully on one or more occasions (one 18 times!), and one had had five X ray treatments with no result. The average dose of radium emanation employed in these cases was 2000–2400 millicurie hours, varying from 1200–3280 millicurie hours; the largest external dose employed was 1020 millicurie hours, and the largest dose given to any one patient was 2400 and 3280 millicurie hours in two doses at a considerable interval. Of radium element the average dose employed was 2000–2400 mg. hours, and the largest dose employed externally 400 mg. hours.

In 33 of the 34 cases complete amenorrhœa has resulted, in 15 immediately after the treatment, in 11 after the occurrence of one period, and in 7 after two or more periods. In one case, at the age of 46, four years after the treatment, the periods have been controlled and are normal in amount but have not yet ceased. In this case treatment was undertaken in the hope that amenorrhœa would result, and that very severe headaches from which the patient suffers at her periods might in this way be relieved, but this result unfortunately has not followed. It is quite likely, however, that a second application might have had the desired effect, the original dose having been the comparatively small one of 2620 millicurie hours.

In the 23 cases complicated by the presence of fibro-myomata in the uterus, the ages varied from 36–55 years. In all the periods were so profuse as to call for treatment. The average dose employed in this series was 2500–3000 millicurie hours, varying from 2000–4248 millicurie hours, the largest external dose used was 1100 millicurie hours, and the largest given to any one patient 2070 and 4248 millicurie hours in two doses; of radium element the average dose was 2400 mg. hours, and the largest external dose used 400 mg. hours. In 16 cases complete amenorrhœa has followed the treatment, in 10 without any further bleeding, in 3 after one period, and in 3 after two or more periods. In two cases a second application was necessary. The first, a patient, 52 years old, had suffered from menorrhagia for several years, and had a fibromyoma of the uterus reaching up to the umbilicus, the sound passing six inches. She was very stout, with a high blood pressure, and quite an unsuitable subject for an abdominal operation. An application of 2070 millicurie hours in 1916 resulted in amenorrhœa lasting seven months; the periods then returned and gradually increased in amount. Four years and a half later, as the periods still continued and were excessive, the patient consented to a second application, and on this occasion a dose of 4248 millicurie hours has resulted in complete amenorrhœa. The second dose should obviously have been given at a shorter interval after the first. In the second case, a patient, 46 years of age, with a uterus containing small fibromyomata, the sound passing 4¼ inches, a first dose of 2425 millicurie hours, followed at an interval of 18 months by a second one of 300 millicurie hours, has resulted in complete cessation of the periods. In this case a troublesome leucorrhœa persisted for some months after the first treatment. In five cases the treatment has been unsuccessful or only partially successful, the periods having returned after one application; these will require further treatment. Two of them have recently been given a second treatment, and the others have been recommended to have this done.

The ages of the 11 patients treated for hæmorrhage not due to any general or pelvic disease varied from 22–42 years. Two were under 30 years of age, eight between 30 and 40, and one 42 years of age. In six of these patients complete amenorrhœa has resulted after one or more periods, two have undergone hysterectomy, and in three the hæmorrhage has been controlled by the treatment. The average dose in these cases varied from 660 to 3186 millicurie hours, the average being 2000–2400 millicurie hours, the largest dose given at one time being 2700 millicurie hours inside the uterus and 1320 millicurie hours through the abdomen over the ovarian regions.

Of the three patients in whom the treatment has been successful in controlling the excessive losses at the periods, the first, a nullipara 22 years of age, had suffered from severe menorrhagia, and had been curetted without any result. She was profoundly anæmic and unable to follow her occupation. The first dose of 2900 millicurie hours was followed by marked diminution in the amount lost at the periods, which became irregular and scanty; this condition lasted for one year, and at the end of that time the periods returned and gradually became excessive again. The administration of a second dose of 2400 millicurie hours, 17 months after the first, has resulted in complete amenorrhœa after one period, and the patient is now, a year later, in very good health and able to work hard. The second case was that of a patient 28 years of age, who had been curetted and had had 15 applications of X rays for excessive periods with little benefit. The menorrhagia followed an attack of influenza shortly after the birth of the last child in January, 1919; an intra-uterine application of 3100 millicurie hours was given in January, 1920, and since then the periods have been irregular and scanty. In the third case, a patient 33 years of age, who had suffered from menorrhagia for some years and had been curetted with no benefit, two applications of 2400 millicurie hours, at an interval of 20 months, followed by an external application of 450 mg. hours 18 months later, have controlled the loss. The periods are now regular and normal in amount, provided that the patient rests at the time.

In two of these 11 cases hysterectomy has been performed; in one, a woman 37 years of age, after one application of 2380 millicurie hours, amenorrhœa resulted for four and a half months. The periods then returned, and the patient went to another hospital, where the uterus was removed. The second case was that of a woman of 40 with severe menorrhagia, in whom complete amenorrhœa for 12 months followed an application of 2400 millicurie hours; at the end of this time there were slight irregular losses with a complaint of pain down both legs, and nine months later the patient underwent subtotal hysterectomy at another hospital. The uterus when removed showed no signs of disease.

The amenorrhœa following the application of radium is no doubt due to its effect upon the ovaries and the destruction of the Graafian follicles which it brings about; it also produces some local destructive effect upon the mucosa of the uterus, but the not infrequent return of the periods in young women shows that these effects may be merely temporary and may be entirely recovered from. No doubt the recurrence of the periods is associated with the maturation of fresh Graafian follicles in the ovaries. It has been suggested that the radium may produce a direct effect upon the tissues of a fibromyoma, but this is doubtful; the shrinkage of these tumours which undoubtedly follows is no doubt due to the onset of the menopause. A sufficient number of cases of pregnancy with the birth of healthy children have been recorded after the use of radium in young women, to show that when the periods return normal pregnancy may occur, and there is no evidence that the children of such pregnancies are more likely to be maldeveloped or deformed, although monstrosities can be produced if pregnant animals are exposed to the action of radium in the early weeks of pregnancy.

The results obtained by those who have employed radium in the treatment of hæmorrhage from the uterus show that it is a valuable and efficient method of controlling excessive hæmorrhage at the menopause; that it can be employed safely for the same purpose in small uncomplicated fibroid tumours of the uterus, and that by its means excessive menorrhagia in young women which resists ordinary methods of treatment can be brought under control.

For the radium used in the treatment of the patients under my care in University College Hospital I am indebted to the Medical Research Council, who have kindly lent the hospital authorities 500 mg. of the salt for purposes of research and treatment. The details of the cases treated in the hospital have been more fully set out in a report furnished to the Council.

THE ANÆSTHETIC ACTION OF PURE ETHER.

By H. H. DALE, M.D., F.R.C.P., F.R.S.,
DEPARTMENT OF BIOCHEMISTRY AND PHARMACOLOGY, THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH, HAMPSTEAD;

C. F. HADFIELD, M.D.,
ASSISTANT ANÆSTHETIST, ST. BARTHOLOMEW'S HOSPITAL;

AND

H. KING, D.Sc.,
DEPARTMENT OF BIOCHEMISTRY AND PHARMACOLOGY, THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH.

Ether has been used since 1846 to produce surgical anæsthesia. Practically all the innumerable investigations of its action in this direction have proceeded upon the assumption that the essential anæsthetic properties were due to diethyl-ether itself, and that the impurities which commercial samples usually contain might complicate the effect by their irritant properties, but would make no significant contribution to the anæsthetic action. A very exhaustive review of the work on ether and its properties up to 1911 is given by Baskerville and Hamor,[1] and, if before that date suggestions that really pure ether was deficient in anæsthetic properties had been made, it is clear that they had not commanded serious attention. In all laboratory investigations of the mechanism of anæsthesia, in which parallels have been established between intensity of anæsthetic action and various physical properties—lipoid solubility, surface activity, &c.—ether has always formed an important member of the series of compounds examined; and the correspondence established between anæsthetic properties and such physical constants have had reference to those of diethyl-ether itself and not of any impurity contained in it. So that the proposition that perfectly pure ether was devoid of anæsthetic properties, if established, would involve not merely some practical change in the preparation of ether for anæsthetic purposes, but a wholesale revision of laboratory data on which the current theories of anæsthesia have been founded. It might entail the abandonment of all theories relating anæsthetic to physical properties, unless, indeed, it could be shown that the partition coefficient of ether between water and oily solvents, its action in lowering the surface-tension at a water-air surface, its aggregating effect on protein sols, and all its other known physical properties, were determined not by the properties of pure ether itself, but by the presence of traces of impurities.

One would expect that a proposition of such revolutionary importance would only be put forward with the support of abundant and exactly documented evidence. During the past six years it has been made from two different quarters. In 1917 J. H. Cotton[2] stated that he had been able, by carefully purifying ether, to deprive it of its anæsthetic properties. An animal subjected to the action of such purified ether was narcotised—i.e., apparently, rendered drowsy and quiescent—but remained hyperæsthetic, responding with abnormal vigour to stimuli. Cotton attributed the anæsthetic property of ordinary ether to the presence of small quantities of dissolved gases, ethylene and carbon dioxide being those identified. The addition of either of these gases to pure ether was stated by Cotton to confer upon it remarkable anæsthetic properties, so that an animal so little narcotised as to be able to walk about the room was rendered completely analgesic, while a human patient could be deprived of all sensation of pain by its administration in quantities not sufficient to cloud the consciousness or affect the power of speech. Following these indications, an American firm introduced a preparation consisting of purified ether, in which ethylene and carbon dioxide were dissolved in the proportions of 2 per cent. and 0·5 per cent. respectively. The question whether ethylene by itself has any anæsthetic action is at least in doubt. There are early records of its trial, as by Nunneley,[3] of Leeds, about 1849; but there is certainly nothing in such records to suggest such potency for ethylene that the addition of 2 per cent. of it to ether could have the alleged effect. In recent years Lumbard,[4] a user of Cotton's ether, states definitely that ethylene alone acts simply as an asphyxiant, like nitrogen. Carbon dioxide is normally present in the air of the lungs in the proportion of about 5 per cent. No immediate explanation is therefore available for the suggested action of these gases in imparting to ether its anæsthetic properties. In default of such, and in view of the somewhat meagre nature of the direct evidence provided by Cotton in support of his statements, it is not surprising that his conclusions were not generally accepted.

In June, 1921, a paper was published by Wallis and Hewer[5] on a New General Anæsthetic. In the first section of the paper, for which Dr. Mackenzie Wallis is responsible, the statement that perfectly pure ether has no anæsthetic properties is implied, though it is not made in exactly that form. It is stated, for example, that "pure ether . . . when freshly prepared can be given in large quantities to animals without producing anæsthesia," and, again, that "the purer the sample, the more of it is required to produce anæsthesia." Later in the paper, although the possession of some anæsthetic properties by pure ether is not specifically denied, reference is made to its use as "a vehicle for the anæsthetic compound," and it is stated that "certain ketones in the ether were largely responsible for the anæsthetic properties of the ether," and that pure ether was used as a "volatile solvent" for the "mixture of ketones." The impression is therefore given that if ether itself has any anæsthetic properties at all, it has them in a subsidiary and even insignificant degree, so that its real function in the preparation of a good "anæsthetic ether" is to serve as a volatile vehicle for the truly and potently anæsthetising "ketones." On some other points it is difficult to be certain of Dr. Wallis's meaning. Apparently his method was to take crude ether, distil it from finely-powdered permanganate to remove irritating impurities, and then dry it by shaking with anhydrous copper sulphate. After such treatment the ether contained a less volatile, pleasantly smelling residue, which "proved to contain ketones." These, being identified as the "essential element," can be artificially added to strengthen the anæsthetic properties. The significance of the gases of Cotton's ether, which Wallis also added, was, apparently, only to intensify the anæsthetic action of the mixed ketones, with which they are held to form "a loose chemical combination."

The practical outcome is the recommendation, as a general anæsthetic, of a mixture prepared by taking ether, purified by treatment with permanganate and copper sulphate, and adding to it, in unspecified amount, a mixture of ketones (identified only as comprising those in the middle of the series) which has previously been treated with carbon dioxide and ethylene. Dr. Wallis states that "the preparation of this anæsthetic, according to the method described above, has been undertaken by Messrs. Savory and Moore, who have now placed it on the market under the name 'Ethanesal.'"

Our own investigations have been directed to two points.

1. We desired to settle, to our own satisfaction, the questions of great theoretical as well as practical importance, raised by the statement that pure ether has little or no anæsthetic action.

2. We have examined the preparation known as "ethanesal."

The chemical work has been carried out by H. King, the animal experiments by H. H. Dale, with valuable cöoperation from Dr. J. H. Burn, and the trials on human patients by C. F. Hadfield.

I. *The Action of Perfectly Pure Ether.*

(*a*) *Preparation.*

The preparation of absolute diethyl oxide was carried out by one of us (H. K.) as follows. The starting material was absolute ethyl alcohol, which was fractionated through a 12-bulb, pear-form still-head, the fraction boiling at 78° C. being collected. This was converted into ether by the sulphuric acid process and fractionated through the same column to free from the main bulk of unchanged alcohol. The ether was washed with 3 N – caustic soda, and with successive portions of water. One litre of such ether was boiled gently under reflux with 25 gr. of finely-powdered potassium permanganate for eight hours. The presence of the water in the wet ether facilitates the interchange of oxidisable material, as potassium permanganate is insoluble in dry ether. On the following day 25 g. of powdered caustic potash were added to the mixture, and the boiling continued for eight hours. The wet ether distilled through a 12-bulb pear-form column between 34·2° and 34·7° at 751 mm. It was dried over best quality calcium chloride and then allowed to boil gently for eight hours over metallic sodium, and then distilled through the usual column. Apart from the first running the whole distilled between 34·1° and 34·15° at 751 mm. This is in perfect agreement with Wade and Finnemore's[6] boiling-point (34·5° at 760 mm.), as a rise of pressure of 1 mm. causes an increase of boiling-point of about 0·04°, so that at 760 mm. our ether would boil between 34·46° and 34·51°.

We believe the ether so prepared to have been as pure as can be obtained. Bourne and Stehle[7] have recently described the preparation of ether from ethyl iodide and sodium ethoxide. They regard this method as excluding the subsidiary substances to which the anæsthetic properties have been attributed, and find that the ether so prepared is fully active. We regard the procedures to which our own preparation was subjected as excluding even more completely all possible impurities. It was perfectly free from aldehydes, ketones, acids, mercaptans, alcohol, and all other known impurities, including ethylene, which is immediately destroyed by alkaline permanganate.

(*b*) *Tests on Animals.*

This pure, dry ether was first carefully tested in the laboratory on a series of cats by one of us (H. H. D.). The animal was, in each case, gently secured on a table and the ether administered by the open method on a gauze mask, made to fit over the snout. Induction occurred perfectly smoothly and with a rapidity at least equal to that normally seen in this species with ordinary, good anæsthetic ether so administered. Such difference as was observable was entirely attributable to the smaller amount of pharyngeal and tracheal secretion provoked, the pure ether being distinctly less irritant than most specimens of ether sold for anæsthetic purposes. This absence of irritation not only facilitated induction, but enabled deep anæsthesia to be maintained with a smaller quantity of the ether. In one experiment, in which volumes were carefully recorded, a comparison was made between the respective quantities, of the pure ether and of a not very satisfactory commercial sample, required to keep a cat of 3 kg. for one and three-quarter hours under anæsthesia, of such depth that the corneal reflex was just abolished. The volumes were: Pure ether, 65 c.cm.; commercial ether, 100 c.cm. No accuracy is claimed for these figures, the method of administration being the open method, with a gauze mask; but they give some measure of our dissent from the statement that "the purer the sample the more of it is required to produce anæsthesia." Our experience has been the direct opposite of this; the purer the ether, the more easily and smoothly has anæsthesia been induced and maintained in experiments on animals. In some of our experiments with perfectly pure ether, after the cat had been kept deeply anæsthetised for periods up to two hours, the administration was stopped, when the animal recovered consciousness at a normal rate. In later experiments with the same pure ether the arterial blood pressure was recorded after anæsthesia had become complete, and the fullness of the anæsthesia was demonstrated by applying strong electrical stimuli to exposed sensory nerves. The only effect was a small rise of arterial blood pressure, without any trace of movement of voluntary muscles; this having been demonstrated, the animal was killed. In one pair of such experiments, two cats of equal weight and of about the same age and build were taken. One was anæsthetised with the pure ether, and the depth of the anæsthesia confirmed as above. The pure ether used in this case was not made by us from alcohol, but was separated from "ethanesal" and subjected to the rigid purification process described above. The other was anæsthetised on the following day and for the same period with "ethanesal," as bought from the manufacturers, the same tests being applied. The efficiency of "ethanesal" as an anæsthetic was neither better nor perceptibly worse than that of the pure ether. To maintain for the same period the same depth of anæsthesia slightly more of the "ethanesal" was, as a matter of fact, used; but the method was not an exact one, and we attach no importance to the difference observed, except as an indication that the pure ether was not the less efficient of the two.

(*c*) *Effects on Human Patients.*

The good and safe action of our preparation of pure ether as an anæsthetic for animals having been placed beyond doubt, we considered it desirable to confirm its efficiency by using it for patients requiring anæsthesia with ether for surgical operations. The member of our team (C. F. H.) who undertook to administer it in this way was familiar with the effects of various makes of anæsthetic ether, including "ethanesal." The results, like those obtained in experiments on cats, were decisive in favour of the efficiency of perfectly pure ether as an anæsthetic. The number of cases in which pure ether was used to anæsthetise human patients was limited to eight, this being regarded as sufficient to establish or disprove its power to produce surgical anæsthesia. To determine satisfactorily its superiority to other anæsthetic ethers would require a long series of cases, and for this purpose sufficient material was not prepared, it being foreign to the primary object of the investigation.

In most cases a preliminary hypodermic injection of atropine (usually 1/100 gr.) was given, and in one or two this was combined with morphia (⅙ gr.). With this exception no other drug of any kind was used except pure ether. In all cases anæsthesia was induced with a Clover's ether inhaler of the usual type, and in most this was used throughout. Care was taken to avoid any cyanosis, so that the favourable results obtained could not be attributed to the presence of an excess of carbon dioxide. In two instances (Cases 1 and 5) the Clover's inhaler was discarded after induction and an open method substituted. This was not done in all cases in order to economise the pure ether. These open cases were as satisfactory as the closed. The patients selected were those with whom the administrator did not consider it probable that he would encounter any difficulty in maintaining an anæsthesia suitable for the operation with ordinary ether without the assistance of other agents. It will be understood that these observations could only be regarded as secondary to the surgical requirements. This will explain the fact that all the patients happened to be women; the exclusion of men was quite unintentional.

The cases are enumerated in the following table, which includes the age of the patient, the nature of the operation, and the duration of the administration, from the commencement of induction to the end of the operation.

Case.	Age.	Nature of operation.	Duration of operation in mins.
1	60	Colpoperineorraphy.	53
2	19	Dilatation and curetting for dysmenorrhœa.	48
3	50	Drainage of septic finger.	15
4	28	Vaginal Cæsarean section.	45
5	32	Tubercular peritonitis diagnosed as appendicitis. Both tubes were removed through the appendix incision.	50
6	45	Exploration of necrosed phalanges.	17
7	59	Cystoscopy and lumbar nephrectomy.	60
8	33	Dilatation and curetting.	30

A comparison of the rapidity of the onset of anæsthesia in these cases with results obtained using the same method with ordinary ether is difficult to one unaccustomed to make frequent use of this precise routine. The impression left on the mind was that the smoothness and speed of thus reaching surgical anæsthesia were such that, if they were equally obtainable with commercial anæsthetic ether, the advantage of a preliminary exhibition of nitrous oxide or ethyl chloride would be scarcely appreciable.

It is quite unnecessary to describe the cases in detail, but Case 7, as being by no means the most easy subject, may be taken as typical. She was a stout and emphysematous woman of 59 years. Pure ether having been placed in the reservoir of the Clover, the face-piece was applied, and, after a few breaths of air had been allowed, the ether was gradually turned on. There was no struggling or coughing, and very little salivation. The reservoir was rotated as far as 2—i.e., half-way to full—and in five minutes from the commencement the patient had been lifted on to the operating table and the parts were being cleansed preparatory to a cystoscopy. The examination proving satisfactory, she was placed in the lateral position, with a raised bridge under the loin, and lumbar nephrectomy was performed. During the operation the Clover was kept at 1 or 1½. Owing to the emphysema and the position of the patient much air had to be allowed to avoid cyanosis. At the close of the operation it was found that, in all, 4¾ fluid ounces of pure ether had been used. The surgeon, unaware of what anæsthetic was being administered, expressed himself as entirely satisfied with the anæsthesia.

Particulars of the other cases would be little more than repetitions of the above, except in the two cases where the open method gave equally good results. As far as could be judged from so small a series, the recovery and after-effects were certainly no worse than those usually following anæsthetic ether. During the induction the tendency to coughing and salivation certainly appeared to be less than usual. In all cases the surgical anæsthesia was complete, and no complaint was made of rigidity. The only abdominal case was particularly well relaxed, as may be judged from the nature of the operation. One surgeon was so impressed by the rapidity of the induction that he thought that ethyl chloride had been administered.

These cases appear to prove beyond doubt that chemically pure ether is an anæsthetic, at least as satisfactory and effective for the human subject as the best ethers usually sold for that purpose.

We cannot offer any satisfactory explanation for the complete discrepancy between these observations and the statement, definitely made by Cotton, and clearly implied by Wallis's account of his work, that pure ether has, of itself, no anæsthetic properties at all. The process to which our ether was subjected would certainly remove, not only impurities, such as mercaptan and aldehyde, but any traces which might be present of ethylene and ketones, to which the anæsthetic properties of ether have been attributed. Its anæsthetic properties were thereby certainly not impaired. On the other hand, we have the statement, from two different sources, that a purified ether was found to have no true anæsthetic action. The observer in one case (Dr. Hewer) is personally known to one of us as a colleague whose competence and experience in this field are beyond question. It is impossible to suppose that the pure ether which he tested, with a pint of which he was unable to anæsthetise a child of seven, can have had properties similar to those of the pure ether used in our experiments. The recorded data as to the methods of preparation and the other properties of these non-anæsthetic ethers are rather scanty, and those which are given—e.g., the range of boiling-points mentioned by Wallis—are such as to indicate that our ether, in so far as it differed from them at all, differed in being purified more rigidly, and not in containing active impurities. The presence of ketones would cause the boiling-point to rise towards the end of the distillation; that of Wallis's preparation appears to have risen slightly, while ours remained constant to 0·05°C. We must leave the discrepancy, without even a suggestion as to its meaning, and be content to record our conclusion that the failures to obtain anæsthesia with purified ethers have not been due to their purity.

This demonstration of the satisfactory anæsthetic properties of pure ether has seemed to us important, not merely as clearing away difficulties and anomalies from the theory of the subject, but as indicating the true aim of a practical policy. In our opinion efforts to improve the properties of ether, as an anæsthetic for ordinary use, can be most profitably directed to the discovery of methods for rendering and keeping it free from the irritant impurities, which are produced in its preparation, and which, in some cases, are liable to be formed when it is kept in contact with air and exposed to light. It may be doubted whether the tests for purity laid down by the British Pharmacopœia are sufficiently stringent. On this point we are glad to find ourselves in agreement with Wallis and Hewer. There is a large body of information concerning the impurities likely to occur and the tests for their presence. This has been admirably summarised in the paper, above mentioned, by Baskerville and Hamor.[1]

II. "*Ethanesal.*"

As stated above, our experiments with "ethanesal," as now supplied commercially, failed to afford us any evidence of an anæsthetic potency which is not satisfactorily accounted for by that of the purified ether, which is its main constituent. We desired, nevertheless, to observe for ourselves the action of the very potently anæsthetic ketones, which, according to Wallis's statement, it should contain. Several samples of "ethanesal" were accordingly purchased and submitted to fractionation. These investigations failed to reveal the presence of any ketones; the only constituent, apart from ether, present in significant amount was, in the case of all samples examined, normal butyl alcohol.

Chemical Examination of "Ethanesal."

An analytical record of "ethanesal" is given in THE LANCET (1921, vol. i., p. 1309), which shows that 98 per cent. distils below 40·2°, and 2 per cent. above 40·2°, and that it contains a very small amount of a substance oxidised to aldehyde by chromic acid, which presumably is ethyl alcohol.

The samples of "ethanesal" examined by us, and bought at different times on the open market, differ considerably from the above. Three pounds (1360 g.) of "ethanesal" were distilled through a 12-bulb pear-form still-head, when 95·5 per cent. distilled between 33·6° and 34·2° at 755 mm., and consisted of good quality dry ether. The remaining 4·5 per cent. was fractionated through a 17-inch rod-and-disc column, when the following fractions were obtained:—

Up to 110°.	110–117°.	Residue.
5·5 g.	48·8 g.	6·5 g.

The large middle fraction was refractionated and gave the following fractions:—

Up to 116·5°.	116·5–117·5°.	Residue.
8·1 g.	36·6 g.	3·0 g.

On refractionation of the first and last of these fractions, with the first and last of the previous fractionation, the following small fractions were collected:—

(1)	(2)	(3)	(4)	(5)
50–80°.	80–90°.	90–100°.	100–110°.	117°.
0·2 g.	1·9 g.	2·05 g.	0·95 g.	16·8 g.

In this way there were obtained 53·4 g. of pure *n*–butyl alcohol boiling at 117°. It was identified by its odour, its boiling point, by conversion into *n*–butylbenzoate (b.p. 247°–248°), by conversion into *n*–butylacetate, and by its solubility, 1 in 10, in water.

Fractions (1) to (4) were then examined. Fraction (1) 0·2 g. contained some ether which passed off on gently warming, leaving a liquid with the odour of pure ethyl alcohol, and giving crystalline iodoform by the test; there was no odour of acetone. Fractions (2), (3), and (4) all had the odour of *n*–butyl alcohol through insufficient fractionation, (3) and (4), for the same reason, being only partially miscible with water.

The first three fractions also reduced ammoniacal silver nitrate in the cold, (1) and (3) to a slight extent, but (2) very strongly, with production of a silver mirror. This pointed to the presence of an aldehyde, and this was confirmed by the observation that (2), but not (1) and (3), restored the colour instantly to Schiff's reagent. Ketones, if present in any of these fractions, are so in very small proportions, as there was no acetone odour of the simplest ketones, or camphoraceous or peppermint odour of the higher ketones.

To summarise, the samples of "ethanesal" examined contained 95·5 per cent. ether, 4 per cent. of *n*–butyl alcohol, and 0·5 per cent. of a mixture of ethyl alcohol and an aldehyde, and possibly other substances in traces. An examination of what were apparently batch numbers on the bottles showed that the three bottles of "ethanesal" used in the above examination belonged to two different, not consecutive batches. We have since obtained two bottles bearing an earlier batch number than either of these, and an examination gave practically the same result; the added material consisted mainly of *normal* butyl alcohol, boiling at 117° C.

We communicated the substance of the above observations to Messrs. Savory and Moore, who informed us that normal butyl alcohol should not be a constituent of "ethanesal," and that its presence in the samples we had examined must have been due to an error. The question is not one which we can explore further, without knowledge of the composition which "ethanesal" is supposed to have, if correctly prepared, and of the method of its preparation. This information is not at our disposal. It is, of course, well known that *iso*–butyl alcohol can be converted by oxidation to methyl-ethyl-ketone, while similar treatment, applied to *normal* butyl alcohol, would not produce a ketone, but might easily lead to conversion of some of the normal butyl alcohol to butylic aldehyde. If *iso*-butyl alcohol were the normal starting-point, for the production of the "ketones" added to ether to make "ethanesal," obviously the substitution, by error, of *normal* butyl alcohol might lead to a product such as we have examined. Our finding of normal butyl alcohol, with some aldehyde, as the essential accessory constituents in "ethanesal," would then have to be attributed to our curious misfortune in obtaining for examination only such batches as had suffered from this error of preparation. There is, however, a further difficulty in the way of such a supposition. A "fruity" odour is recognised by anæsthetists, and claimed by the manufacturers as a characteristic of "ethanesal." The odour of *normal* butyl alcohol could be so described, and that of the aldehyde is even more distinctly of this type. A mixture of these two has been recognised, by an habitual user of "ethanesal," as having the characteristic "fruity" odour. On the other hand, neither methyl-ethyl-ketone, nor any other ketone with which we are familiar, has an odour resembling this, or obviously suggesting "fruitiness." In default of more precise information we are left in a state of complete uncertainty as to whether any of the numerous published clinical observations of the action of "ethanesal" were carried out with ether containing genuine ketones, or with ether containing *n*-butyl alcohol, of which some portion had been oxidised to butylic aldehyde. Meanwhile, in view of our own failure to detect any real difference between the action of "ethanesal" and that of pure ether separated from it, or independently prepared, we feel justified in waiting for further proof before concluding that the nature of the added constituent would make any serious difference, except to the flavour.

Conclusions.

1. Our own observations give no support to the statements that pure ether is devoid of anæsthetic action, and that the activity in this direction of ordinary ether is due to impurities. On the contrary, so far as the anæsthetic action of ether is affected by purification, it is in our experience improved by the removal of impurities, which irritate the respiratory mucosa and cause excessive secretion, but otherwise unchanged. The purest ether is the best, as an anæsthetic.

2. Samples of "ethanesal," as purchased from the makers, have been found to consist essentially of ether with about 4 per cent. of normal butyl alcohol and a small quantity of an aldehyde. Our observations afford no evidence to warrant the attribution of its anæsthetic properties to any other constituent than the ether. We find no reason for supposing that the presence of the added substances materially affects any property of the ether vapour, except the flavour.

Comments by Dr. R. L. MACKENZIE WALLIS.

The observations made by Dale and his co-workers, and recorded above, call for comment on two main points, viz. (1) the vexed question as to whether chemically pure ether is a potent anæsthetic agent, and (2) the value of added chemical compounds, particularly ketones, as anæsthetic agents. With regard to (1) our work was commenced with this problem uppermost in our minds, since all the work has been concentrated upon the purification of ether. This was emphasised in the paper we published in THE LANCET, 1921, i., 1173. The pure ether was prepared in a similar manner to that described above, but differed slightly in the final stages of purification. After being treated with permanganate, copper sulphate, and sodium, and redistilled after each stage, the ether was allowed to stand in contact with sodium for several weeks. On being again distilled an ether of remarkable purity was obtained possessing a very slight odour, and when given as an anæsthetic proved to be so weak as to be useless. This pure ether was very unstable, and had to be kept in black bottles, and great care taken to avoid shaking. Further, it was always used fresh when trying its effects as an anæsthetic.

The work of Cotton was published at this time, and we were interested in his conclusions, and made attempts to confirm them. The only point on which we found that we were in agreement was on the question of the weak anæsthetic action of pure ether. Finding that the chemically pure ether was a weak anæsthetic, and this conclusion was reached only after much deliberation, and control observations which gave no conceivable outlet for fallacy, our attention was drawn naturally to the factor or factors concerned. In this way the presence of ketones was detected, and the chief ketone appeared to be methyl-ethyl ketone. On adding this in increasing quantities to pure ether the anæsthetic properties were increased and in proportion to the amount added.

Now we have always found that our " detoxicated " ether possessed quite a good anæsthetic action—viz., the ether prepared from trade ether by means of permanganate and anhydrous copper sulphate. This ether, however, was found to vary in its action according to the source of supply of the trade ether. The procedure as finally evolved consisting in making detoxicated ether from one constant supply of ether, each batch being made in exactly the same way. To this detoxicated ether ethyl-methyl ketone was added in the strength of 2 per cent. As so many complaints were made that this mixture was too weak, and even weaker than ordinary anæsthetic ether, the strength of the added ketone was increased to 5 per cent. Since this increase no complaints were received. At the present time we are quite at a loss to explain why the product " ethanesal " was found by Dr. King not to contain ketones, particularly as we are unaware that any departure from the original process had been made.

All recent work has been concentrated upon the anæsthetic action of ketones. A number of ketones do undoubtedly possess anæsthetic or hypnotic action, and some that we have made have proved to be quite potent in this respect. All the observations tended to show that our ether-ketone mixture was a good and reliable anæsthetic, and differed in many respects from ordinary anæsthetic ether. Many of our observations have been confirmed by others, and this alone has stimulated us to pursue the matter further.

We admit that certain forms of pure ether have an anæsthetic action, that our detoxicated ether always has, but that the ether-ketone mixture is better than either, and, furthermore, has a totally different action to either of the other two forms of ether. We are quite at a loss to explain the above observations of Dale and his co-workers, and can only conclude that they have made a very good sample of detoxicated ether.

I am very grateful to Dr. Dale for permitting me to see a copy of the above paper, and for an opportunity of explaining the results obtained by Hewer and myself.

Comments by Dr. C. LANGTON HEWER.

Dr. Dale has been kind enough to let me see a copy of the above paper, and I should like to make the following comments thereon.

In the first place, I should like to make it clear that I am speaking purely as an anæsthetist, as I am not competent to discuss the somewhat intricate organic chemistry involved, and this side of the question has been dealt with by Dr. Mackenzie Wallis.

The first consideration is the *anæsthetic action of pure di-ethyl ether*. The original ether prepared by Dr. Wallis's method was found to produce no appreciable anæsthetic action on animals, and was given to me for trial on human beings. The first cases to which I administered this ether were children. The method used was an open mask with about 20 layers of gauze, and I found that the patients passed into the second or excitement stage of anæsthesia, but it was impossible to produce narcosis within a reasonable time (20 minutes). Nearly one pint of the ether was used in each case. An adult patient (a girl of 19) was next tried, using the ether in a Clover's inhaler. By keeping the indicator at " full " for six minutes (having previously taken about five minutes to rotate it from " 0 "), a light degree of anæsthesia was obtained, but on adopting the open method it was impossible to keep the patient sufficiently still for the operation to proceed, and a change over to ordinary " anæsthetic ether " was made, after which no further trouble was experienced.

The remainder of the pure ether was then given to another anæsthetist (Dr. B. B. Sharp, late resident anæsthetist to St. Bartholomew's Hospital), who employed it on a child of 7. In 15 minutes the child was still struggling violently, and a C.E. mixture was given, with immediate narcotic effect. Dr. Sharp at that time knew nothing of the theories concerning pure ether, and remarked to me that " this ether is no good as an anæsthetic." Since it was obviously impossible to continue indefinitely using this ether, I deemed that sufficient evidence had been obtained that it had no appreciable anæsthetic properties.

Turning next to the evidence of other observers, Dr. Dale has already referred to Dr. Cotton's statement that pure ether is not an anæsthetic, and we need not discuss that further.

In a recent American paper, however (*American Journal of Surgery*, vol. xxxvi., No. 7), Dr. Paul Cassidy makes two observations on Cotton Process ether: (1) That using the open method it was an indifferent anæsthetic; and (2) that if the cans were opened within a special inhaler devised by himself a much stronger anæsthetic action occurred. He then analysed the ether and found that—

$$\left.\begin{array}{rl} 5 & \text{mins.} \\ 10 & ,, \\ 40 & ,, \end{array}\right\} \begin{array}{c}\text{after opening the can}\\ \text{it contained}\end{array} \left\{\begin{array}{l} 2{\cdot}24\ \% \\ 1{\cdot}87\ \% \\ 0{\cdot}26\ \% \end{array}\right\} \begin{array}{c}\text{ethylene at}\\ 79{\cdot}7^\circ\ \text{F.}\end{array}$$

Now since Cotton Process ether contains ethylene, carbon dioxide, pure ether, and a trace of alcohol only, the only variable factor was the gaseous constituents (carbon dioxide and ethylene), and Cassidy therefore showed that when these had been lost the residue (pure ether) was a weaker anæsthetic.

In the same number of the *American Journal of Surgery* there also appeared an article by Dr. Webster entitled " Some New Anæsthetic Ethers," in which he describes his experiences with Cotton Process ether given by the open method—i.e., pure ether with little or no ethylene. He says: " By this method I found to my great disappointment that the induction period was on the average longer than with other ethers. Often 16 to 18 minutes after commencing induction the patient only reached the second stage of anæsthesia. The excitement stage was considerably prolonged, and the quantity of anæsthetic was greater than with the make in ordinary use in this institution."

We thus see that at least five independent observers have found that pure ether has at any rate a considerably weaker anæsthetic action than has ordinary ether. In this connexion I should like to point out that when "ethanesal" was first prepared it contained only 1 per cent. ketones, but the manufacturers received so many letters from anæsthetists saying that the anæsthetic was much weaker than ether that the percentage of ketones was gradually raised to 5. Further, the purified ether used as the basis of "ethanesal" does have some anæsthetic properties, since it has only been "detoxicated"—i.e., mercaptans, &c., removed. It is unnecessary and indeed commercially impossible to purify the ether to the extent employed in the preliminary experiments, and consequently some of the original ketones remain in it.

Dr. Dale has kindly provided me with a small amount of the ether which Dr. King prepared, and I have used it on one case (a woman of 24). The induction period was 5½ minutes, using a Clover's inhaler, and the anæsthesia obtained was satisfactory. I used more anæsthetic than I should have expected with "ethanesal," but about the same as with ordinary ether. I should like to point out, however, that this sample of ether had a much more pungent odour than the original specimen prepared by Dr. Wallis. I am quite prepared to admit, on the other hand, that the ether prepared by Dr. King is an anæsthetic, thus agreeing with the results obtained by Dr. Hadfield.

The next point concerns *mercaptans*, and since Dr. Dale agrees with our findings that they are extremely toxic and should be removed from anæsthetic ether, I will not discuss the matter further.

Thirdly, there arises the question of the *anæsthetic action of ketones*. Dr. Wallis has shown that animals can be anæsthetised with a mixture of methyl-ethyl and vinyl-ethyl ketones provided that the temperature was high enough for adequate vaporisation. I have tried this mixture on children, and although the apparatus was crude (a drip-feed to an aluminium plate heated by a resistance coil fixed into the top of a mask), yet it at least demonstrated the anæsthetic action of these ketones. The practical difficulties of evolving a suitable vaporiser are great, and we have not yet been able to obtain a satisfactory apparatus. I might also mention that methyl-phenyl ketone (hypnone) has been used as a hypnotic for many years, and such substances as camphor and menthol have also been used as local analgesics.

Fourthly, we pass to the *anæsthetic action of ethylene and carbon dioxide*. We found that pure ether + carbon dioxide had no more anæsthetic action than the ether alone, unless one employs the gas in the patient's expired air as in a closed apparatus. The ethylene question has been partially discussed before, but I might add that we found that pure ether + ethylene gave a good anæsthetic if used before the gas passed out of solution. As Dr. Wallis showed in his original paper, this action was probably due to the ketones contained in the ethylene, and latterly it has been found unnecessary to add any ethylene to "ethanesal."

In conclusion, I would like to state that I have no doubt of the accuracy of the work of Dale and his colleagues, and I have recorded the above observations from the anæsthetist's standpoint only. I make no attempt to explain the apparent discrepancies in the results, and there is no doubt that the whole subject calls for a considerable amount of further work. At the same time, however, I should like to say that I have now used "ethanesal" in over 4000 cases, and am convinced that whatever may be its exact chemical composition, it gives, on the average, better results than any anæsthetic ether that I have tried.

CHRONIC SEPTIC SPLENOMEGALY.

By GORDON WARD, M.D. LOND.

I VENTURE to set forth the following views with regard to a certain class of chronic splenomegalies because they have been of material assistance to me in both diagnosis and treatment. Although many physicians are well acquainted with a syndrome to which may be given the name "chronic septic splenomegaly," I am not aware of any detailed consideration of the subject from a clinico-pathological point of view. Considerations of space oblige me to treat the subject in didactic form, but I must point out that in arriving at the views here put forward I owe a great deal to many other authors in England, on the Continent, in America, and particularly in tropical countries. A large number of cases reported as Egyptian splenomegaly, and under various other names, appear to me to be examples of chronic septic splenomegaly differing in the variability of the ætiological factor but not in the essentials of the resulting pathological process.

Symptoms.

Chronic septic splenomegaly is a constant syndrome arising in many different circumstances and owning a variety of ætiological factors. A typical case should show the following characteristics: (1) a chronic septic focus, localised perhaps about the teeth, or on the heart valves or in the bowel (and then very difficult to identify); (2) a massive splenomegaly, considerable in degree, hard, and somewhat tender on palpation; (3) in the early stages, leucocytosis and slight or no anæmia, but later increasing anæmia with less leucocytosis or actual leucopenia; (4) in favourable cases complete recovery following the eradication of sepsis. These are the cardinal features commonly encountered and easy of recognition. Amongst other less constant features are: (5) fever; (6) hæmorrhages, epistaxis commonly, purpura not very rarely, but hæmatemesis scarcely ever; (7) enlargement of liver, of lymph glands, and of lymphadenoid tissues generally; (8) cirrhosis of those tissues from fibrosis of the affected areas.

The generalised reaction of lymphadenoid tissues constitutes the whole anatomical basis of the syndrome, but usually it is the splenomegaly which attracts attention and in many cases any marked enlargement of glands or liver may be looked for in vain. All of which, it may be noted, is also true of another generalised lymphadenoid reaction—namely, spleno-medullary leukæmia.

Ætiology.

In all cases septic organisms (as opposed to those which produce a specific histological picture—e.g., *B. tuberculosis*) seem to be the causal factors. This is proven in some cases by the prompt recovery when sepsis is removed[1] or following the use of vaccines when splenectomy had failed to cause improvement,[2] and is further suggested by the success of Lemaire[3] and Kristjanson[4] in transmitting the disease to dogs. Many cases have been ordinarily recognised as depending on sepsis—e.g., those described as endocarditis with splenomegaly[5] or as oral sepsis with splenomegaly.[6]

Pathology and Histology.

It appears that at first the septic organisms produce such results as we associate with their presence in any case—e.g., fever, pain, and leucocytosis. Later a more distinctly selective action on the lymphadenoid and connective (which are potentially lymphadenoid) tissues appears. There is then enlargement of the spleen and perhaps also of liver and glands. The blood now begins to deteriorate, and this is presumptive evidence of a like effect on the marrow. At first all such enlargements are somewhat acute and tender and the histology is that of a typhoid spleen, and were the sepsis as quickly terminated as in that disease it would as quickly return to normal. There follows a stage in which the spleen is very large and indurated and the marrow is still further affected, so that the polymorph reaction fails and we find leucopenia. There is, however, often some red-cell attempt at reaction as shown by the presence of nucleated red cells. Later there may be hæmorrhages and death, or the condition may become so attenuated that there is time for contraction and fibrosis of the reacting tissues, manifested by cirrhosis of the liver and spleen.

The histology is that of chronic inflammation wherever encountered—i.e., it is a fibroblastic and/or plasma-cell reaction with no specific features. There is no excess of pigment in any of the tissues.

Diagnosis.

Diagnosis is by elimination. Various considerations will probably suffice to eliminate leukæmia, acholuric jaundice, malaria, kala-azar, Gaucher's disease, erythræmia, Hodgkin's disease, von Jaksch's syndrome, syphilis, tuberculosis, cancer with bone metastases, and such rarities as histoplasmosis, toxoplasmosis, and Krempf's splenomegaly. Where doubt remains, as may often be the case, the presence of a discoverable septic focus and tenderness of the spleen assume considerable importance, especially if the blood picture shows the early stage. Primary tuberculosis of the spleen is especially difficult to differentiate, but there the symptoms are usually more severe and the spleen very tender. In the blood signs of two processes are seen: first, a polymorph leucocytosis without eosinophilia gives place to a leucopenia in which the eosinophils may more than hold their own (a low-grade eosinophilia is common in many kinds of splenomegaly); and secondly, a more or less normal red-cell count with a low index is replaced by definite anæmia with a rising index.

Treatment.

This means eradication of sepsis. I have no short cut to intestinal sepsis to recommend, although I feel with Hollins[7] that this is what is most required. However, I have seen excellent results when dysentery was properly treated and when oral sepsis was eradicated.[8]

Relationship to Banti's Disease and Idiopathic Splenic Anæmia.

I believe that the conception of chronic septic splenomegaly set out above solves the ætiological problem in a great majority of the cases hitherto reported as splenic anæmia or as Banti's disease. There is reason to suppose that the sepsis in these cases is mostly intestinal, and therefore easily overlooked and not productive of any marked fever, &c. No doubt there remains a residuum of cases which must still be called idiopathic splenic anæmia and which await further investigation.

Groups of Cases Described under Different Titles.

1. *Splenomegaly with Endocarditis.*—This was well described by West[9] so long as 25 years ago and of late years has had increasing attention. Besides the papers of Libman[5] one may note the fully described case of Parkes Weber[10] and the case of Riesman[11] in which the spleen was removed. The splenic condition in an acute endocarditis is that of enteric and a variety of other conditions, but when the process becomes one of chronic continuing infection the syndrome of chronic septic splenomegaly appears and it is in this condition that one finds all stages of the syndrome. It is, however, complicated by signs of heart failure which obscure the clinical picture.

2. *Egyptian Splenomegaly.*—This type appears to depend on intestinal sepsis, the site of infection being provided by dysenteric ulcers or determined by the presence of helminth parasites. It has been reported from many parts of the world—e.g., by Archibald,[2] Day and Ferguson,[12] Footner and Archibald,[13] for the Sudan and North Africa, Duncan Whyte[14] and Maxwell[15] for China, Wooley[16] for the Philippines, and Sprawson and Mackie[17] for Mesopotamia. I think the cases of Rose Bradford[18] were of this type, as also some of my own seen amongst the troops in France, and probably also some at least of those cited by Luccarelli[19] under the title "War Splenomegaly?" I cannot accept the distinction suggested in an annotation in THE LANCET in 1921.[20] It is interesting to note that one of my cases had a heavy trichomonas infection, for an apparently similar case is referred to by Luzzatto.[21]

3. *Enteritis and Splenomegaly.*—This is especially met with in children, and the septic origin is commonly accepted—e.g., by Riviere[22] and Ashby.[23] Morse in a long paper refers the splenomegaly to disturbance of nutrition, but notes that gastro-intestinal disorders were present in each of his 40 cases.[24]

4. *Oral Sepsis and Splenomegaly.*—The cases of Wynter and others have already been cited. In one of my own cases extractions at once relieved serious symptoms and the spleen returned to normal. The normal spleen, however, prolapsed into the lower part of the abdomen and still (two years later) gives rise to some trouble which probably depends on torsion of the pedicle.

5. *Senile Anæmia.*—Cases of chronic splenomegaly have been described under this name by Kurpjuweit.[25] Hasenfeld reported two further cases in 1911. These may have been of the chronic septic type, and it would appear doubtful whether it was worth while to class them separately.

There are scattered through the literature many cases in which one feels that the possibility of a chronic septic splenomegaly has been overlooked, while unnecessary and invalid distinctions have been based on particular blood examinations or other variable features.

Conclusions.

I venture to conclude from individual cases, from my own mistakes, and from a review of the literature: (*a*) That the underlying pathological process is the same in all chronic splenomegalies of septic origin; (*b*) that the recognition of this origin will remove a large number of cases from the groups of idiopathic splenic anæmia and Banti's disease; and (*c*) that it will greatly assist treatment.

NOTE.—Since the above was written there has appeared an important paper by A. G. Gibson[26] in which he deals with chronic inflammatory diseases of the spleen. In a personal communication he states, "My own point of view is ætiology first and last, on the view that only by working on these lines will the real relationships of disease be apparent." I am a little disposed to dispute this thesis, but by no means willing to depreciate the value of the work which it inspires, and anyone interested in the subject should consult the various papers which Gibson has published. In *Medical Science* for May, 1921, will be found extracts from various papers on splenomegaly, but since then, with the exception of Gibson's article, no paper of first-class importance has come to my notice.

ATTACKS OF ARRESTED RESPIRATION IN THE NEW-BORN.

By GEORGE F. STILL, M.D. Camb., F.R.C.P. Lond.,
PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET; PROFESSOR OF DISEASES OF CHILDREN, KING'S COLLEGE HOSPITAL.

In the majority of text-books of midwifery and diseases of children asphyxia of the new-born is described under the traditional headings "asphyxia livida" and "asphyxia pallida," and some books go further and describe how in some infants respiration is never fully established and after some hours or days of hurried, feeble breathing respiration gradually fails altogether and the infant dies, a condition sometimes described as "extra-uterine asphyxia," and attributed to congenital atelectasis.

The condition to which I wish to draw attention is a form of respiratory failure differing from any of these and occurring not only in the first few days after birth, but sometimes in infants some weeks old. In the few cases which I have seen it has been regarded by the medical men in attendance as a condition with which they were quite unfamiliar, so that it seems worth while to give some detailed description of it.

Reuss, in his text-book "Diseases of the New-Born," refers to cyanotic attacks in connexion with premature infants and also under the heading "atelectasis." He lays no stress upon the sudden arrest of respiration, which is the striking feature of the cases to which I am referring. Perhaps I shall best describe them by drawing up first a composite picture based on the very small number of five cases which constitute the whole of my experience of this condition, which is therefore probably not frequent.

General Features.

An infant aged, it may be, only a few hours or it may be a few weeks, has given no cause for anxiety; the labour perhaps was normal, there was no asphyxia at birth and all seems going well, when the infant who has been left apparently perfectly well a few minutes previously in its cot, is found leaden-coloured or pale, having entirely ceased to breathe; artificial respiration starts the infant breathing again, and by the time the doctor arrives the whole upset sounds like a false alarm, the infant is lying placidly in its cot with good colour, breathing perfectly comfortably, and the unwary might think that the story was exaggerated. But in a few hours the infant is again found in the same condition; without the slightest sign or warning respiration has stopped, and only by prompt artificial respiration is life again saved. So the story goes on for a day or two, and then probably in one of the attacks breathing cannot be restored and the infant dies.

From five cases one cannot ascertain at what age such attacks are most liable to occur, but I can state positively that they are not limited to the first day or two after birth. One of my cases began his attack at 4 weeks, and another when 4 weeks 5 days old. Any delimitation of the new-born period must be purely arbitrary, but if Reuss's limit of "the first two or three weeks" is adopted neither of these two cases was new-born. The age at which the attacks began were respectively about 16 hours, 26¾ hours, 5 days, 4 weeks, and 4 weeks and 5 days.

Antecedent Conditions.

Unfortunately I have no notes of the character of the labour except in two, in neither of which were instruments used. In one of these, the case in which the attacks began at the age of 26¾ hours, labour had lasted 34 hours and presentation was occipito-posterior, and the mother had had ⅓ gr. morphia nine hours before the child was born, and two doses of bromide and chloral, 20 gr. of each, twice before the morphia; chloroform was given on and off during the labour. I mention these details, which I have kept only in that one case, because it might be suggested that sedative drugs given to the mother may have an inhibitory effect upon the respiratory centre, as happens in opium poisoning. That such a cause is generally responsible for these attacks is not likely, for the effect of drugs given to the mother during the labour would hardly account for the onset of such attacks so late as four weeks after birth.

The infants with these attacks are not necessarily feeble or ill-nourished, the infant who began them at 26¾ hours old weighed 9 lb. at birth, and the infant who began them at 4 weeks and 5 days, though he had weighed only 5¼ lb. at birth, weighed 8 lb. when the attacks began. Asphyxia at birth is certainly not a necessary antecedent; in the case just mentioned it was specially noted that he breathed at once, and the infant whose mother had had morphia was stated to have had no asphyxia; it did not cry well at birth, but started breathing readily with slight smacking. Of my five cases four were boys; it remains to be seen whether this predominance of males is more than a coincidence in such a small series. If prolonged labour specially predisposes to these attacks, one might expect them to occur more often in the first-born than in later children; but so far as my own small figures go this would not appear to be so, for in three of them I noted the number of the pregnancy: they were the fourth, fifth, and eighth pregnancies respectively.

Onset and Nature of Attacks.

Reverting now to the character of the attack, I should like to lay stress upon certain points. The individual attacks came on without any apparent reason, they were not traceable to crying or flatulence or any such exciting cause. They have, in my experience, usually occurred when the infant was lying placidly in its cradle. The onset is absolutely silent, there is no crying, no struggling, no stridor, no apparent distress, the infant simply ceases to breathe, and apparently, as a rule, this cessation is abrupt and complete. In one only of my cases, a fatal one, the respiration gradually became slower, then ceased, and returned gradually after an interval of one and a half minutes, so that the attack was very like an exaggerated Cheyne-Stokes respiration except that it occurred as a single attack, not in a continuous series. In all the rest there was no gradation, respiration simply ceased. A very striking feature of all of them was the perfectly healthy good colour of the infant during the intervals between attacks. The actual attack was accompanied by more or less cyanosis, and this occurred so nearly simultaneously with the cessation of respiration that it was difficult to say which came first, cyanosis or arrest of respiration. In some of the cases the respiration was somewhat shallow and quick in the intervals, but in none was this so marked as to have caused any anxiety if the attacks had not occurred; indeed, I do not think it would have attracted attention at all. The heart continues to beat steadily for some time after the respiration has ceased. I have particularly noted in some of my cases how strong and healthy the heart beat was in the intervals between the attacks, so that the latter would seem not to be due to any general feebleness, but rather to some affection of the respiratory centre. There seems to be no reason to suppose that the respiration would start again spontaneously except when the arrest is of the gradual character, which occurred in one case already mentioned, and, indeed, even with artificial respiration it is sometimes difficult to restart it, so that there is grave risk to life in any attack. The number of attacks varies greatly. In one case there were four in one day and two the next, and then the attacks ceased and the child recovered. In another there were six or seven attacks in the 24 hours, and these continued to recur for seven days before death occurred.

Prognosis.

The outlook would seem to be very black; only one of my five cases recovered. Here, again, I would emphasise the deceptiveness of the infant's appearance in the intervals between the attacks. A fairly nourished infant with good pink colour, lying comfortably in its cradle with no sign of anything amiss in heart or lungs, is not suggestive of any particular respiratory danger. It was of just such an infant as this that I gave a hopeful prognosis to the parents, and five minutes later, before I had left the house, another attack occurred which proved fatal. Obviously such attacks as these may have an important medico-legal bearing, for it is possible that the first attack of this kind might prove fatal, and, indeed, would almost certainly do so unless someone happened to observe the cessation of breathing, so that death might easily be attributed to overlaying or some more sinister cause, when an apparently healthy infant had without any apparent illness been found dead in its mother's bed or in its cot.

What is the meaning of these attacks? Are they primarily of pulmonary origin, or are they, if I may so say, syncopal attacks in the respiratory centre? It is difficult to see how atelectasis, assumed to date from birth, can account for attacks postponed until the infant is several weeks old, which has happened in some of my cases. Moreover, the condition of the infant in the interval between the attacks is, as I have pointed out, curiously unsuggestive of respiratory trouble. I have made two post-mortem examinations. One showed a certain amount of collapse in the bases of both lungs and probably a very early commencing broncho-pneumonic process; but the attacks had occurred several times daily for seven days before death, so that it was at least as likely that the atelectasis was the result as that it was the cause of the attacks. In the other case there was more extensive atelectasis, the greater part of the right lung and part of the left lower lobe being atelectatic, but here again, who shall say whether the atelectasis was the result or the cause? The infant had several attacks daily from the age of 5 days old, until he died at the age of 15 days. Is it not likely, indeed almost certain, that more or less extensive collapse would result from such repeated bouts of arrest of breathing? The appearance of the attacks, their sudden onset, and the good condition of the infant during the intervals is more suggestive of some affection of the respiratory centre than of any secondary asphyxia from insufficient expansion of the lung.

Treatment.

If life is to be saved in these cases, it is all important that the sudden and absolutely silent onset of the attacks should be borne in mind. It is essential that the infant should be watched closely by someone night and day until the attacks have been entirely absent for some days. At any moment artificial respiration may be the only hope of saving the child's life, and the nurse or mother must be instructed accordingly. I have had oxygen used in the attacks, and it probably helps in re-establishing respiration; it is certainly worth while to devote unremitting attention to these infants, for although recovery may be the exception, there is undoubtedly the possibility of saving them, and this will depend largely upon careful watching for the first moment of arrest of breathing. Any delay in beginning artificial respiration can only diminish the chance of recovery.

THE TREATMENT OF CHRONIC INTESTINAL STASIS BY COLLOIDAL KAOLIN.

BY ALFRED C. JORDAN, C.B.E., M.D. CAMB., M.R.C.P. LOND.,
CORRESPONDING FOREIGN MEMBER, BELGIAN ROYAL ACADEMY OF MEDICINE.

KAOLIN, in one form or another, has long been in use as a therapeutic agent. In radiological practice I have found it a convenient substance for opaque enemata mixed with barium sulphate and warm water. In colloidal form it is in a state of very fine subdivision. When I began to study the properties of colloidal kaolin as an adsorbent of intestinal toxins, I was struck with its efficacy, and the benefit derived from its administration in stasis. Others, to whom I introduced it, reported similar favourable results, and the time has come to publish an account of its use in the treatment of stasis.

Intestinal stasis is, I am convinced, at the root of most of the disorders of digestion, and the toxæmia of stasis is responsible for a number of local and general disorders. These have been fully described and explained by Sir Arbuthnot Lane in his classic writings; they are also dealt with in my papers on stasis.[1]

Surgical Treatment of Stasis.

Stasis demands surgical intervention: (*a*) when it has led to a local disease, such as gastric or duodenal ulcer, gall-stones, an appendix abscess, or an obstructive kink; (*b*) when the stasis has been allowed to advance to the stage of permanent incurable disease of the large intestine, so that excision of the diseased bowel offers the only chance of cure. Dental surgery must repair the havoc wrought in the mouth by neglected stasis. Surgical intervention will become rare when stasis is recognised early, and treated before organic mischief has arisen.

Non-Surgical Treatment of Stasis.

The successful treatment of stasis demands an exact knowledge of the pathological conditions present, obtained by (*a*) a complete history and full account of the symptoms; (*b*) a careful physical examination; (*c*) a chemical, histological, and bacteriological investigation of urine and fæces, and a chemical and histological examination of the blood; and (*d*) a complete X ray investigation of the alimentary tract with a bismuth meal and a barium enema.

(*a*) Stasis usually starts in the large intestine, and the start can be traced to infancy or early childhood. The prevention of constipation and of gastric distension in childhood does much to ensure a healthy youth and a vigorous adult life. Take a typical case of stasis as seen in middle life, say between the ages of 45 and 55. The patient looks careworn and unhappy; his skin is dry and wrinkled, and he looks older than his years. He complains of headache and aching limbs; his muscles are stiff and easily fatigued, his joints rheumatic; he is subject to lumbago, sciatica, or neuritis. His digestion is faulty and he suffers from flatulence and "heart-burn" with foul breath and a coated tongue. There is constipation, perhaps alternating with a form of "diarrhœa" characterised by loose stools, full of mucus, and very offensive. The patient is short of breath on slight exertion.

(*b*) The physical examination of the abdomen reveals thickening of the wall of the iliac colon and of the terminal ileum; pressure upon these parts causes pain. Thickening (and pain on pressure) may be felt also over the pylorus, at the duodeno-jejunal junction and in the position of the gall-bladder. A succussion splash is often elicited in the stomach.

(*c*) The pathologist finds in the urine the products of intestinal putrefaction, and in the fæces the bacteria that are causing putrefaction. He also finds an excess of mucus from the catarrhal mucous membrane.

(*d*) The radiologist finds some or all the abnormal conditions described in my papers on stasis. In a typical case the pelvic colon is elongated; the splenic flexure is sharply angulated in a high position; the cæcum, ascending colon, and transverse colon are dropped. The descending and iliac colon are narrowed by tonic spasm due to catarrh of the mucous membrane (mucous colitis). The catarrh causes exaggerated segmentation of the cæcum, ascending and transverse colon. Small amounts of fæcal material are forced with mucus through the narrowed descending and iliac colon, while the main fæcal mass remains imprisoned in the cæcum and ascending colon. A barium enema shows not only the elongation of the pelvic colon and the sharp bend of the splenic flexure, but also the large capacity of the cæcum and ascending colon. The habitual overdistension of the cæcum stretches the ileo-cæcal valve, and allows some of the enema fluid to leak through the valve into the ileum. Incompetence of the ileo-cæcal valve leads to spasm of the ileo-cæcal sphincter, and this causes stasis in the lower coils of the ileum, and hypertrophic thickening of the terminal coil of the ileum. Ileal stasis gives rise to kinking at the duodeno-jejunal junction and distension of the duodenum. Pyloric spasm is set up, and causes delay in the evacuation of the stomach. The pyloric spasm of stasis is exceedingly persistent and obstinate.

---

[1] Proc. Roy. Soc. Med., 1911, vol. v.; 1913, vol. vi.; 1915, vol. viii. Brit. Med. Jour., 1913, ii., 915; 1920, ii., 959. Practit., February, 1913. THE LANCET, 1920, i., 756. Also Sir Arbuthnot Lane's Operative Treatment of Chronic Intestinal Stasis, Chapters 2 and 13.

Treatment.

How are these changes best dealt with? The X ray findings having excluded all conditions which require surgical intervention, treatment may be prescribed with every prospect of success. The chief measures are the following:—

1. The dropping of the stomach and large intestine is corrected by a Curtis belt.

2. Stasis in the large intestine is met by prescribing liquid paraffin. If the pelvic colon is much elongated warm saline enemata should be given in addition.

3. Spasm of the sphincters (pyloric and ileo-cæcal) and spasmodic constriction of the large intestine are best overcome by belladonna, 8 or 10 minims of the tincture with a little bicarbonate of soda twice a day after food.

4. Decomposition in the intestines is dealt with most effectively by means of colloidal kaolin, a dessert-spoonful of the kaolin powder if taken in half a tumbler of hot water night and morning.

5. The septic contents of the lower ileal coils must be cleared out by salines. Streptococcal infection of the intestines most often occurs in the lower ileum; few streptococci pass on into the cæcum and still fewer reach the rectum. This has been proved by withdrawing material from the intestines during abdominal operations. Bacteriologists are able to grow streptococcal cultures from the fæces by giving their patients lactose (with the object of increasing the growth of streptococci for the time being), and a saline aperient to propel the streptococcal chyle into and through the large intestine. Applying this experience, colloidal kaolin is given to adsorb the intestinal toxins, and a saline aperient to drive onward the contents of the lower ileum.

All the above measures aid one another in breaking the vicious circle of stasis. The paraffin helps the Curtis belt to support the dropped viscera; it makes the fæces specifically lighter than the watery contents of the small intestine, so that the large intestine tends to float up, instead of being the heaviest part of the intestines as it is when full of solid fæces. The belt, in its turn, helps the action of the paraffin and saline aperient by supporting the viscera, abolishing kinks, and preventing traction of the viscera upon the mesenteries. The belladonna helps in three ways: (1) it opens the "gates" (i.e., the sphincters); (2) it diminishes spasmodic narrowing of the large intestine; (3) it antagonises the vaso-constrictor action of the intestinal bacterial toxins, and thus acts as a physiological antidote to these toxins.

Colloidal Kaolin in Stasis.

The advantages to be derived from colloidal kaolin are: 1. It adsorbs bacterial poisons in the intestines, and is a potent and efficient agent in rendering these poisons innocuous. 2. It soothes the mucous membrane. 3. It has a very useful mechanical action in the large intestine. In conjunction with paraffin it converts the fæces into a soft, homogeneous mass which passes through the big bowel readily. Patients who have given up liquid paraffin because it "runs through" are able to take it in conjunction with colloidal kaolin. With a little care in dosage it is possible to maintain motions that are smooth, soft, and almost odourless like those of a baby.

In severe cases of intestinal stasis the large intestine is elongated, dropped, and angulated, its walls catarrhal and sodden, its mucous membrane congested and perhaps eroded, its contents hard and foul and covered with offensive mucus. The lower coils of the small intestine lie in a "pool" in the pelvis, full of stagnant fluid which teems with virulent organisms, pouring out poisonous products, to be absorbed into the circulation unchecked. This stagnant pool has but one outlet—through the ileo-cæcal valve—and this outlet is barred by spasm. This is no exaggerated picture, it is the condition which exists in an appreciable proportion of civilised men and women. The *least* adverse result is a general decline in health and vigour. Those who are less able to resist the poisons suffer from headache and various forms of digestive disturbance, or from spasmodic asthma. Others are victims of lumbago, neuritis, and rheumatic fibrositis. Still worse off are those who become tuberculous or cancerous, and most unfortunate are the epileptics and the insane.

Now see how rational and effective is the treatment. Start with paraffin and a Curtis belt. The bowel is supported so that it no longer drags on the mesentery, kinks are abolished, the fæces are softened (by the paraffin) so that they can be evacuated with little effort. The belt aids the feeble toxic abdominal muscles during defæcation. Now add colloidal kaolin. Most of the kaolin collects in the lower ileal pool, adsorbs toxins there, and makes the foul contents of the lower ileum innocuous. Next add belladonna. It opens the sphincter and widens the narrowed large intestine. Lastly add a saline. It clears out the lower ileal cesspool, already "treated" with kaolin. The saline and the paraffin together effect the speedy evacuation of the large intestine. If the pelvic colon is much elongated a course of enemata is needed to complete the evacuation. Colloidal kaolin may most usefully be added to the enema fluid—an ounce of kaolin to each pint of warm enema fluid.

Vaccines.—Autogenous vaccines are of considerable help in many cases.

Diet.—Correct feeding is of great importance in the treatment of stasis. The details of diet must vary to suit individual needs, but certain principles of diet may be laid down. Articles to avoid are: (*a*) Those which irritate the mucous membranes, especially alcohol and sharp spices (mustard, cayenne, &c.); (*b*) those which decompose readily in the intestines. Meat is the most important of these, and it includes poultry and game. Excess of sugars should be avoided as encouraging streptococci.

Foods to take are: (1) Fresh fish; (2) fresh dairy produce—eggs, milk, cream, butter, cheese; (3) fresh garden produce—lettuce, fruits, and vegetables; (4) grains of all kinds, including coarse oatmeal; (5) nuts. Large meals should be avoided; the "static" stomach cannot deal with them.

Régime.—The principles of régime may be tabulated thus: 1. Avoid fatigue, whether physical or mental. 2. Retire early and spend a long night in bed. When commencing treatment, it is often well to advise three weeks of complete recumbency, and to impose a rest of two hours after lunch for some weeks more. 3. Cultivate regular habits, and acquire the faculty of having a soft (not liquid) fæcal evacuation after each meal. A routine visit to the lavatory after each meal may remain unrewarded at first, but a few weeks' education will enable the bowel to respond satisfactorily—with the aid of paraffin, kaolin, and belladonna.

Results of Treatment of Stasis.—The rewards of perseverance with treatment on the lines I have laid down are manifold. Dyspepsia, heart-burn, flatulence, and many other everyday disorders of digestion yield. The appetite improves; the patients gain weight, improve in complexion, and acquire a healthy look. They enjoy a grateful feeling of comfort, vigour, and good health. Rheumatism, neuritis, asthma, and many other toxæmic troubles of stasis clear up in a most gratifying way under colloidal kaolin saline in conjunction with paraffin and belladonna.

Colloidal Kaolin in Common Ailments.—There are many common ailments—not primarily or necessarily due to stasis—in which alimentary toxæmia occurs, and where colloidal kaolin has been found most useful, such as bronchitis, pharyngitis, and infantile diarrhœa. In the epidemic illnesses of children (measles, whooping-cough, &c.) colloidal kaolin is a great stand-by. It helps the children through the bad days with the minimum of discomfort to themselves and of anxiety to the parents and nurses. A dose of calomel is a good prelude to the treatment with kaolin, belladonna, and paraffin. The morning sickness of pregnancy is alleviated, and kept at bay in many instances. During lactation both mother and child reap the benefit of the cleansing action of colloidal kaolin saline, given to the mother with paraffin if need be.

Colloidal Kaolin in Tropical Affections.—Colloidal kaolin, with or without saline, is the best remedy known in colitis and dysentery. It checks the diarrhœa and soothes and heals the eroded or ulcerated mucous membrane. Asiatic cholera has lost most of its terrors since it has been shown to yield to frequent draughts of kaolin in watery suspension. Further experience will undoubtedly add to the range of usefulness of colloidal kaolin. Colloidal kaolin of uniform composition and free from impurities, organic as well as inorganic, have been prepared for me by the Collasan Company (20, Holborn Viaduct E.C. 1), who supply it, by itself and with saline aperient, under the names of "Collasan" and "Collasan-Saline." When it is deemed advisable to prescribe collasan without saline, or to prescribe the saline separately, the following formula is recommended by Dr. A. White Robertson :—

Collasan (colloidal kaolin) .. 3½ oz. | Water .. 8½ oz.

Add the water to the collasan in a large basin, stirring thoroughly to form a fine cream. Now add, constantly stirring, 1 oz. of mucilage of tragacanth and 10 minims of oil of peppermint (or oil of dill). A port-wine glassful to be taken every six hours.

Clinical and Laboratory Notes.

GONORRHŒA IN WOMEN

TREATED WITH CONTRAMINE PESSARIES.

By G. W. RUNDLE, L.R.C.P. & S. EDIN.,
L.R.F.P.S. GLASG.,
RESIDENT MEDICAL OFFICER, LONDON LOCK HOSPITAL FOR WOMEN.

IN June, 1921, I published some notes[1] on the treatment of gonorrhœa in women with intramine pessaries, showing the very satisfactory manner in which the discharge vanished. Though this method of treatment proved superior to all others, it had one drawback, in that 8 per cent. of the cases developed a local dermatitis. To obviate this development, Mr. J. E. R. McDonagh has elaborated a more active preparation of sulphur, di-ethyl-ammonium di-ethyl-di-thio-carbamate (contramine), which has all the advantages of intramine, with none of the disadvantages. Contramine pessaries have been used in the London Lock Hospital for over a year, and not a single case of dermatitis has resulted. Further, the discharge disappears quicker and the erosions heal more rapidly than was the case with intramine pessaries.

The course consists of a pessary placed against the cervix nightly when the patient is in the recumbent position, the pessary being retained in position by a gauze tampon, which is taken out next morning. One of the great advantages of contramine pessary treatment for a discharge of any origin over the douching and speculum treatment is that patients can insert these pessaries at night by themselves in secret. Patients like this pessary treatment because, apart from the rapidity of clearing the discharge, it is obviously convenient for a patient to be able to keep the pessaries, say in a chocolate box, and administer one to herself nightly unobserved, even when other females are in the same room. To carry out vaginal treatment in secret with a douche is a great strain on a patient's ingenuity and happiness.

Contramine pessaries should only be used when the discharge is chronic. One hundred cases have been treated; in only seven cases was the gonococcus found before treatment, and in none was it found after treatment, though all cases had a definite vaginal discharge. But most observers agree, I think, that to find the gonococcus in the adult female in a chronic discharge is very difficult. These cases received 30–40 pessaries each, no other treatment was prescribed, and they were kept under observation for two months without treatment before being discharged. So far only four cases have relapsed.

---

[1] THE LANCET, 1921, ii., 802.

FRACTURE OF THE HEAD OF THE FIBULA.

By A. W. LEMARCHAND, M.R.C.S. ENG.

THE following is a record of an unusual accident which occurred to a man, aged 56, who was standing close by the side line, watching a Rugby football match. A full back went to charge an opposing forward, missed his man, fell, and struck his head against the outer side of this spectator's knee. The accompanying tracing of an X ray photograph of the knee shows the fracture of the head of the fibula which resulted. There was no displacement and no appreciably increased lateral movement.

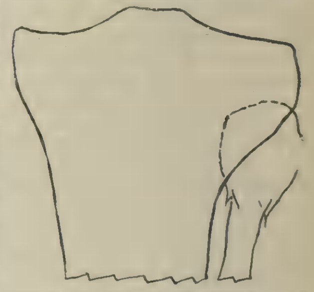

Diagram traced from X ray photograph of fractured head of fibula.

I should be glad to hear if any reader of THE LANCET who has had experience of a similar injury can state whether any trouble followed in the nerve which lies behind the head of the fibula.

Barnstaple.

A CASE OF "INFECTIOUS MONONUCLEOSIS."

By P. D. H. CHAPMAN, M.B., B.CH. CAMB.,
M.R.C.S. ENG.

THE interesting annotation on Infectious Mononucleosis and its possible causation, which appeared in THE LANCET of Feb. 17th, prompts me to relate a recent case of mine, which corresponded very closely to the description of this disease. The patient was a boy of 17; the first symptoms were enlargement of cervical glands and pyrexia, the throat remaining normal in appearance until the ninth day of illness, when a very acute follicular tonsillitis occurred. By this time the submaxillary, axillary, and inguinal glands were also enlarged and pyrexia had been continuous. The white cell count on the fifth day was 15,000 per c.mm.; the differential count was: mononuclear lymphocytes, 56 per cent.; polymorphonuclear leucocytes, 38 per cent.; hyalines, 6 per cent.; eosinophiles, nil. The progress of the case was uneventful, the blood count returned to normal, and all glands became no longer palpable within 20 days of onset. It is difficult to see how an infection of the throat could be considered as a cause of the disease in this case.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OTOLOGY.

A MEETING of this section was held on Feb. 16th, when Sir **CHARLES BALLANCE**, Vice-President of the section, occupied the chair.

Mr. G. J. **JENKINS** delivered a contribution entitled

Osteitis Deformans and Otosclerosis: a Pathological and Clinical Comparison,

and showed a number of micro-photographs of the conditions found. He considered the subject under the following headings: 1. A comparison of the pathological changes in bone in osteitis deformans and otosclerosis respectively. 2. A comparison of the clinical aspects of osteitis deformans with otosclerosis. 3. Conclusions. He showed serial sections from the temporal bones of three subjects: (*a*) female, aged 84, with cephalic osteitis deformans; (*b*) the temporal bone of a male, aged 61, who had osteitis deformans of the skull and long bones; (*c*) from a male, aged 41, who had otosclerosis and severe tinnitus. This series was selected because it showed the general affection of the capsule of the labyrinth. The microscopical appearance in both conditions was that of osteoporosis. The trabeculæ of bone in osteitis deformans were more coarse, and the lamellæ more distinct than in otosclerosis. The dense bony capsule of the labyrinth afforded most resistance to the progress of osteitis deformans. The large osteoclasts, obvious in all the sections, were more numerous in otosclerosis specimens. The proliferation of fibroblasts was more evident in otosclerosis; but the fibrous tissue was the more prominent feature in osteitis deformans. In some parts the marrow of the bone was in close contact with the endostium. In both diseases he found a deposit of what was probably fibrinous material, and this took the selective stain for amorphous fibrin. In both conditions the stapes remained free from disease. Bone conduction was usually diminished in otosclerosis; this was more evident with low tones than with high. The Rinné test in typical otosclerosis he regarded as of the first importance; a negative Rinné to tones below 200 was one of the valuable signs of that disease. Typical otosclerosis cases heard better with electrical aids; this latter fact carried one a long way in diagnosis.

The symptoms and signs of typical cases were due to the site of activity of the disease, which could produce other forms of deafness if it occurred in other parts of the labyrinth. Sometimes he had found typical otosclerosis symptoms in one ear, and in the other ear only a loss of bone conduction. He was inclined to look upon otosclerosis rather as an accident of disease than as a disease sui generis. In all cases of osteitis deformans in which the skull bones were markedly affected the patients were deaf. This deafness was not accidental. If there was a certain degree of similarity, clinically and pathologically, to what did these observations lead? Were the two conditions identical? Against this view was the absence of any hereditary tendency in osteitis deformans. Otosclerosis usually began in early life, osteitis deformans was recognised late in life. In osteitis deformans one did not find a family history of otosclerosis. If the two diseases were due to the same fundamental cause, the difference in distribution must depend on the individual; and in otosclerosis the peculiarity which rendered the person liable to the affection must be hereditary. The causes of these bone diseases might be quite distinct, but it was one characteristic common to both which produced the change in the labyrinth and the consequent similarity in the signs of the deafness. All the patients had had the Wassermann test carried out twice at two institutions each, and all had been X rayed to make sure of the distribution. Mr. Jenkins gave the clinical details of nine cases.

Sir **CHARLES BALLANCE** congratulated Mr. Jenkins on the beauty of his specimens. It was a very important subject to be investigated, and he hoped the research into the intimate pathology of these two diseases, especially osteitis deformans, would be continued. He had operated on these cases in the old days, but had always found it impossible to get beyond the disease in the skull; there was always a local recurrence. Fibrinous deposits were described as occurring in the cochlea; these usually meant inflammation.

Mr. **ALBERT A. GRAY** said he thought this was the first time that the similarity of the changes in bone in otosclerosis and those in other bone diseases had been demonstrated. He had often suspected there might be a similar change accounting for the spontaneous fractures occurring in locomotor ataxy. He did not feel quite satisfied that otosclerosis always began with evidence of nerve deafness. The earliest case of otosclerosis of which he had cut sections was one in which the deafness had existed three years, and there was very definite bone change at that stage. It would be interesting to know what was the view of pathologists as to the causation of osteitis deformans. Both the diseases under discussion might be nutritional—i.e., the blood supply to and the nutrition of the bone might be affected in both.

Mr. **SYDNEY SCOTT** spoke of his examination of a number of cases of osteitis deformans many years ago. One of the sections was exactly like one Mr. Jenkins showed on the present occasion. The osteoporosis in his cases was diffuse. It was curious that osteitis deformans patients should so often succumb to malignant disease. The occurrence of fibrinous exudate might be a mere coincidence; he did not know that it denoted any change in the labyrinthine fluid.

Mr. **RITCHIE ROGER** said that of 75 cases reported at least 6 showed a definite hereditary history. Some help in arriving at the ætiology might be obtained by a study of the secretion of the endocrine glands.

Sir J. **DUNDAS-GRANT** described some cases of osteitis deformans of his own which had obstructive deafness. Also one in which the trouble was vertigo and deafness, with probably some optic neuritis. He diagnosed cerebellar tumour. The man was received into an infirmary, where he was said to have osteitis deformans. The post-mortem revealed a cerebellar tumour.

Mr. **JENKINS** replied, pointing out the importance of distinguishing between internal-ear deafness and nerve deafness. At present the nomenclature was too general. He could not be certain that it was fibrin in the labyrinth, it was a fibrinous deposit, which gave Gram-positive in staining.

Cases of interest were shown by Sir J. **DUNDAS-GRANT**, Mr. J. F. **O'MALLEY**, Mr. E. D. **DAVIS**, and Dr. H. J. **BANKS-DAVIS**.

SECTION OF OPHTHALMOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A CLINICAL meeting was held at the Royal London Ophthalmic Hospital (Moorfields) on Feb. 9th, Mr. A. L. **WHITEHEAD**, the President, being in the chair.

Optic Atrophy after Herpes Ophthalmicus.

Mr. **LESLIE PATON** exhibited an interesting example of this condition. The patient, a woman aged 67, had, at Easter of last year, a bad attack of ophthalmic herpes which affected all the branches of the first division of the fifth nerve on the left side. Faint nebulæ resulting from corneal vesicles were left. On recovering from the herpes the patient found she could not see with her left eye, and it was discovered that the left pupil did not respond to direct stimulus, but reacted well on consensual stimulation. There was a slight reaction to concentrated light. Ophthalmoscopically, an opaque white disc was seen, but the lamina cribrosa could not be seen. There was no obvious disturbance of retinal pigment round the edges of the disc. The calibre of the vessels was reduced. The complication of ophthalmic herpes by true optic neuritis was comparatively rare. Mr. Paton had not seen a case until last summer when a patient, aged 35 years, of Mr. Adams, of Oxford, was seen by him. When her right eye was opened after the herpes had subsided it was found to be quite blind ; the pupil was semi-dilated and did not react to light at all. Her tension was normal, and the ophthalmoscope revealed an absolutely atrophic disc. In Sir Jonathan Hutchinson's classical account of the condition (Ophthalmic Hospital Reports, vol. v.) he said the globe was never affected except when the naso-ciliary branch of the first division of the fifth was involved ; but there were exceptions to this. Still, this statement was of great service in prognosis. Mr. Paton reminded the meeting of reports of other cases with the same complication. Evidence of other cranial nerve involvements was more frequent. In the epidemic of last spring he saw three or four cases of diplopia, and later, one in which the sixth nerve was affected. Statistics showed that the third nerve was more often concerned, while the nerve-supply of the iris and ciliary muscle was not uncommonly affected. One of his cases had no superficial vesicle on the cornea, but there was a well-marked deep keratitis with irido-cyclitis. In last year's epidemic he had noticed definite hypotony. The evidence available seemed to show that the changes in the optic nerve were secondary to the peripheral changes in the circulation produced as the result of the herpes. It was important to differentiate cases in which the herpes occurred from an implication of the Gasserian ganglion, or the branches of the fifth, by any other associated intracranial condition, from the true cases of herpes ophthalmicus, due probably to an infection of the Gasserian ganglion. As to the supposed relationship between this infection and chicken-pox, further information was much needed, but it was steadily accumulating ; he had shown a case of optic atrophy resulting from retro-bulbar neuritis during chicken-pox, and in several cases he had traced a relationship between ophthalmic herpes developing in adults with cases of chicken-pox in children.

Mr. R. **Pickard** related a case of his own in which persistent blindness of the affected eye followed an attack of the disease, another case which seemed to show an association between herpes and chicken-pox. —Mr. W. H. **McMullen** spoke of a case now under his care in which optic atrophy followed herpes.—Mr. H. W. M. **Kendall** described a case showing an intimate relation between chicken-pox in a child and herpes in his mother.

Cicatrisation of the Retina.

Mr. **Frank Juler** showed a child the subject of this condition. He had been sent from school in the ordinary way because of defective vision, and the ophthalmoscope revealed a half circle of fibrous-looking tissue, involving the macular region, and along the edge of the tissue there were hæmorrhages. Six months earlier a rubber ball had struck that eye, and it might have ruptured the retina and the choroid beneath, and hæmorrhage therefrom having now become organised.

Bilateral Tubercle of Choroid in a Cat.

Mr. J. B. **Lawford** and Mr. H. **Neame** showed sections from the eyes of a kitten 5 months old, which was found to have bilateral tubercle of the choroid, with detachment of the retina. The animal had not wasted, nor refused food, which was chiefly the household milk. Complete blindness existed, and it had come on rapidly. The pupils were dilated and did not react to light. In each eye was an extensive detachment of retina, and no part of either fundus was visible. Its end was brought about by chloroform. Another kitten from the same litter was quite healthy and well grown, and there seemed to be no abnormality in the eyes.

Mr. **Neame** described the pathological condition found. The posterior part of the choroid was definitely thickened and the retina completely detached. There was some conjunctival and episcleral infection, and some cells in the angle of the anterior chamber and round the ciliary processes. Even a long search through the sections did not disclose tubercle bacilli, but that was not an uncommon experience in tuberculous conditions, especially in animals' eyes, and it did not contradict the diagnosis of tubercle.

Sub-Hyaloid Hæmorrhage.—Band Keratitis.

Mr. M. S. **Mayou** exhibited a girl who, after rubbing her eye, had a sub-hyaloid hæmorrhage. The blood count was normal.

Mr. A. C. **Hudson** showed two patients with band keratitis, in neither of whom could any cause be discovered. In one of the patients he scraped away the film with such a good result that the vision was improved from less than 6/60 to 6/12. Laboratory investigation of the specimen did not lead to a very definite opinion as to its nature, but it was not thought to be calcareous.

Mr. **Paton** agreed that these patients were very tolerant to scraping, and gave some experiences supporting this.

Atrophic Patches at Macula.

Mr. F. A. **Williamson-Noble** showed a married woman, aged 36, with this condition. She had had several operations for tubercle, and since 1920 the vision in the left eye had been getting worse, until it was less than 6/60. The vision in the right eye was also only 6/60. In the right eye the internal limiting membrane could be seen to be pushed forward 3 D., for vessels could be traced coming from the disc and the parallax showed the membrane to be in front of the rest of the disc. In the lowest part of the patch was an impairment, suggesting that a hole existed in the membrane.

Mr. R. A. **Greeves** suggested that the appearance might be due to a thin-walled cyst in that area.—Mr. **Paton** thought Mr. Greeves's suggestion a likely one. The fibres of Müller might have been ruptured, and the membrana limitans interna lifted forward ; he had seen that occur in the course of papillœdema.—Mr. **Juler** suggested there might be a new membrane altogether ; such were not uncommonly seen in degenerate eyes. If a new membrane formed in front of the retina, the membrane might reach outwards so as to bring a supply of blood to itself.

Cyst of Sclero-Corneal Margin.

Mr. **Kendall** showed a patient, aged 17, with this condition. A week ago a foreign body entered the eye, and he sought advice the following morning, when the cyst now seen was noticed. It had been hidden by the eyelids. There was no remote history of an injury, but the eye might have been injured in childhood.

Sir W. **Lister** regarded it as an implantation cyst. It was difficult to obtain any history of injury in such cases, as also in implantation cysts of the iris ; but an injury could occur without the knowledge of the parents.

Mr. **Colley**, Mr. **Williamson-Noble**, Miss **Ida Mann**, and Mr. **Baranoff** showed cases of injury, and of coloboma in disc and iris.

SECTION OF PATHOLOGY.

A meeting of this section was held on Feb. 20th, Prof. J. C. G. **Ledingham**, F.R.S., the President, being in the chair.

Fermentative Reactions of Different Types of B. Diphtheriæ.

Dr. C. C. **Okell** and Miss E. M. **Baxter** gave an account of an investigation into the fermentative reactions of the serological types of virulent *B. diphtheriæ* described by Eagleton and Baxter, as well as their unclassified cultures. The most useful agents for differentiating *B. diphtheriæ* appeared to be glucose, saccharose, lactose, dextrin, glycerine, and litmus milk. Glucose and saccharose appeared to be the sugars of most practical use in differentiating the diphtherial from the diphtheroid group. Of 100 strains of virulent organisms all, when quite pure, fermented glucose and failed to ferment saccharose. Dextrin was fermented by all but one strain of poor growth. A number of avirulent organisms agreed in every particular, morphological and fermentative, with the virulent forms. The authors, in summarising their conclusions, stated that all serological types of virulent *B. diphtheriæ* that they had so far examined had practically identical sugar reactions. Fermentative reactions at present available could not be used to distinguish between the various serological types or between virulent and avirulent forms.

Dr. S. C. **Dyke** communicated the results of an investigation into the

Inheritance of the Specific Isoagglutinable Substances of the Red Cells,

undertaken by Dr. C. H. Budge and himself in the maternity ward of St. Thomas's Hospital. Ninety-seven unions were observed with 98 offspring. In no case was it found that the isoagglutinable substances A or B of the red cells appeared in the offspring without having been previously present in the blood of the parents, this being in conformance with the hypothesis of von Dungern and Hirschfeld. Placental blood was used for ascertaining the blood group of the infants; it was found that in only 16 out of the 98 cases investigated was it possible to allot the placental blood to its group by means of the agglutinins of the serum; in the remaining 82 the agglutinins were either completely or partly absent. In determining the group of the offspring reliance was consequently placed upon the reaction of the red cells. It was pointed out that 32 of the 98 babies examined appeared to be of a different group from their mothers.

The Disruptive Phenomena in Gunshot Injuries: Their Physics.

Prof. S. G. **Shattock**, F.R.S., observed that whatever clinical peculiarities gunshot injuries presented, their proper pathological interest as injuries was limited to the fact that the velocity of the missile produced special effects known as explosive, or better as disruptive. As was well known, Prof. Vernon Boys some years ago succeeded in photographing bullets soon after their leaving the rifle, and demonstrated the presence of a conical air-wave accompanying the missile. At first the displacement of air seemed of some importance, but it was quite negligible, although, under the name of "windage," much had once been attributed to it. Amongst other proofs, the author had found that on firing with a service rifle and pointed modern British bullet, at 20 feet, through screens of tissue paper tensely stretched on wooden frames, the aperture in the paper very little exceeded the size of the bullet.

Spin of the Bullet.—The late Sir Victor Horsley attributed the disruptive effects chiefly to this factor. A close study of the plaster casts made from the cavities produced in soft clay by firing directly and at close range into the latter did not, in Prof. Shattock's opinion, confirm the evidence of this: the ridges on such casts presented only slight indications of any obliquity —not more than would be due to the open spiral of the rifling. The most conclusive proof of the absence of spin was furnished by the study of British bullets fired into sand. The apex showed fine scratches due to the sand, which were not spiral but longitudinal. The disruptive factor is thus reduced to that of forward velocity acting upon a mobile and practically incompressible medium, the lung alone excepted, in which no such disruption took place. The lateral disrupting movement was imparted to the medium by the intense compression in front of the bullet, which compression is also exerted sideways, since the conical point simultaneously acts as a wedge. It was in the skull that the disruptive phenomenon was most marked. The effect is still often supposed to be hydrostatic, but it was a hydrodynamic one, as shown by experiments made upon objects with a free exit; for example, upon tins empty and others filled with water, the vessels being freely open at the top. Two clear circular holes were made in the first; in the other, the back was split into large triangular everted flaps. The rate of the wave transmitted by the water is equal to that of the bullet, which as soon as it impinges is accompanied by the receding wave of the water. Similar results were obtained in human and sheep skulls when inverted and filled with water, the foramen magnum being left freely open. If the brain is left in, the same comminution takes place.

The British Rifle Bullet.—It had been asserted (Prof. Stargardt, 1914) that the British missile was designed for expansion; that on striking, the momentum carried the leaden core over the aluminium cone and split the mantle. A study of bullets fired experimentally through calvariæ of different thicknesses, the bullets being recovered in cotton waste behind, showed that on perforating dense bone the momentum caused the lead to splay out or mushroom at the open base, and not at the junction of the lead and aluminium. In the first degree the mantle was evenly turned back over a projecting rim of the lead; in the later, the mantle was split and recurved, the splitting starting at times where scored by the rifling. On compressing bullets in a vice Prof. Shattock found that some of the lead was expressed from the open base, but no displacement occurred over the harder aluminium cone. The cupro-nickel mantle of the British bullet, however, was less resistant than the German of steel. This Prof. Shattock was able to prove by taking samples of each mantle, placing a steel ball over the open end of each and testing by increasing loads the pressure they would withstand. The British mantle began to yield or open out under a load of 180 lb.; the German under a load of 390 lb.

Experimental Carcinoma in the Rabbit.

Dr. J. A. **Murray** showed preparations of two squamous-celled carcinomata of the skin which he had produced in rabbits as the result of eight months' painting with an ethereal extract of tar. The latent period of the development of these tumours corresponded fairly closely with that seen in the mouse. They were likely to prove of great value in the investigation of therapeutic measures, since the rabbit was a particularly favourable animal for this purpose.

ULSTER MEDICAL SOCIETY.

A laboratory meeting was held on Feb. 15th, Prof. R. J. **Johnstone**, the President, being in the chair.

Prof. W. St. Clair **Symmers** demonstrated the presence of melanosis in the tissues of the ox and also some early uterine cancers.

Prof. W. J. **Wilson** read a short paper on reduction of sulfonites by certain bacteria in media containing a fermentable carbohydrate and metallic salts, illustrated by a number of interesting specimens exhibiting clearly the appearance of sulphide in the presence of iron salts.

Dr. J. A. **Milroy** described a recent accurate method for the determination of the reaction of solutions (Michaelis' method). In this method a series of indicators showing one colour change (colourless-yellow) is employed. The method enables accurate pH measurements to be made without the use of buffer solutions and has the great advantages of simplicity and rapidity.

Dr. S. **Andrews** described and demonstrated various methods for the detection of traces of blood in urine and fæces.

Prof. J. E. **McIlwaine** showed a series of electrocardiograms along with form records of the perfused mammalian heart and the frog's heart. The effects of various cardiac drugs on their records were described and illustrated.

Dr. C. H. G. **McAfee** gave an interesting description of the work done by students in a class of practical pharmacology which was held for the first time during the present winter session. The action of various drugs on blood-vessels, the heart, and intestinal muscle was shown in a series of interesting demonstrations, and the records obtained in the general class work were exhibited.

MEDICAL SOCIETY OF LONDON.

A MEETING of this Society was held on Feb. 26th, Lord **DAWSON**, the President, being in the chair.

Mr. **JAMES BERRY** introduced a discussion on the

VARIOUS METHODS OF TREATMENT OF CANCER OF THE TONGUE.

He said that statistics on this subject might be misleading, even those in the excellent report of the Boston Symposium on Carcinoma of Jaws, Tongue, and Cheeks. A common error was to describe a certain percentage of apparent successes amongst so many cases, of which a certain number were advanced cases, and not to mention the proportion of advanced cases amongst the recoveries. Statistics accompanied by sufficient detail about each case to enable the reader to judge of its severity would be most valuable, but were rare. Besides his own operative experience he had had unusually large opportunities of seeing the work of others, and so realised that the ordinary mode of extension of cancer of the tongue was backwards and downwards towards the hyoid bone. Operations for such a cancer should often extend widely in the two directions, and this could not be sufficiently effected by an intrabuccal operation. After emphasising the importance of early treatment of tongue lesions and of the excision of all doubtful ulcers, &c., for microscopic examination, Mr. Berry stated his belief that an external or submaxillary operation offered the best chance of relief for advanced cases, for which, even if not curative, the operation afforded relief of the distressing condition within the mouth. He did not agree with procedures involving splitting the cheek or dividing the lower jaw. The disease was essentially a local one with very little tendency to distant metastasis, but owed its malignancy to its tendency to affect the cervical lymphatic glands at an early stage. Early free removal of the primary growth with a removal en bloc of the nearest lymphatic glands offered hope of permanent cure. But if the growth originated in the posterior part of the tongue the deeper cervical glands (especially the post-pharyngeal glands), which were early affected, could not be removed en bloc and permanent cure could hardly be expected. He doubted whether the so-called "block dissection," with removal of jugular veins and sterno-mastoid, was ever worth doing. It was seldom necessary for cases where the growth was situated on the anterior part of the tongue, and he believed generally useless for advanced cases when the growth was situated posteriorly. Further, he thought it probable that unsuccessful attempts to dissect out affected glands merely favoured the spread of the disease. The class of case which Mr. Berry had dealt with had been mainly those of cancer of the middle and posterior thirds of the tongue.

Operative Treatment.

For small carcinomata of the anterior half of the tongue, not involving the floor of the mouth, he believed that the removal of one-half of the tongue, followed later by the free removal en bloc of all structures in the sub-maxillary, and if necessary the submental, region of one or both sides was generally the best operation. For larger growths, wherever situated, and for all growths of the middle and posterior thirds, he had for many years practised an external operation. He had done about 27 of these operations. A curved incision was made from the symphysis menti to the angle of the jaw, similar to that used in the classical operation for ligature of the lingual artery, and the flap containing platysma turned back. The entire submaxillary region was then cleared, the lingual and facial arteries being early identified, ligated far back, and divided. The digastric was divided and the mylohyoid detached from the jaw, and the muscles running into the front of the tongue divided close to the jaw, so that the dissection could be carried right down to the mucosa of the floor of the mouth, which was preserved intact. The buccal part of the operation consisted of the usual splitting of the tongue in the middle line. The mucosa was incised in the floor of the mouth from outside, and the tongue drawn out through the submaxillary wound and divided as far back as necessary, so that the affected portion of the tongue was removed in one piece with the whole of the submaxillary tissues. A sponge held in the wound prevented blood from running into the larynx during the final division. The operation was almost bloodless. The wound left was partly drawn together by two catgut sutures and a drainage-tube left in the middle of the wound and brought out through a separate incision one inch lower. Mr. Berry did not find intratracheal anæsthesia or preliminary laryngotomy necessary, and he had never had trouble from blood entering the larynx. Illustrations and drawings of the operation were shown, as well as specimens removed at operation.

Treatment by Diathermy.

Mr. W. H. **CLAYTON-GREENE** said that from the American statistics one fact emerged—if carcinomatous glands were present very few cases lived for three years. Upon all other points he agreed with Mr. Berry that statistics were useless unless the nature and position of the growth were stated. His own results had been so poor that he took to diathermy for the removal of intrabuccal carcinomata. For diathermy he claimed these advantages: (1) It was possible by this means alone to destroy the tongue right back to the epiglottis by an operation through the mouth; (2) there was no danger of the implantation of cancer cells in the operation wound. As a disadvantage it was stated, and rightly, that diathermy produced a septic slough, but the slough only became septic after an interval during which the lymphatics had become sealed off. He had only had one serious case of sepsis among 60 operations by diathermy within the mouth. As regards treatment, there were in America two schools—that of Crile, who advocated a bilateral "block dissection" of the neck with removal of the tongue later, and that of Quick, who maintained that no operation was of any avail. While not subscribing altogether to the latter view, he agreed that the results of surgical treatment, even in the Mayo Clinic, were most depressing. The operation he now performed resembled in some ways that described by Mr. Berry. Through an external excision, he made a clean sweep of the submaxillary region, and tied the facial and lingual arteries or the external carotid. The tongue was then removed by diathermy. He had now abandoned the "block dissection" since he had noticed that in many cases it appeared to favour recurrence in the neck, and that the results of this large operation were worse than those of the more limited ones. The same had been noted by others with regard to operation for cancer in other places, notably in the breast. He regarded the glands as constituting nature's barrier to the disease, and thought that in future more attention would be devoted to the extensive removal of the primary growth.

Treatment by Radium.

Mr. A. E. **HAYWARD PINCH** described his experiences of the treatment of cancer of the tongue at the Radium Institute. Of about 600 such cases, quite 580 were inoperable when first seen, and 300 could only be described as appalling. While radium could do something to help these people, it could not be claimed to have effected a single cure at the Radium Institute, although he did know of one case apparently cured by radium. This was the case of a physician in the West of England, who refused operation for a small growth of the tip of the tongue, confidently diagnosed by two surgeons as carcinomatous. He had treated himself by the application to the growth of a small tube containing 10 mg. of radium for one hour daily for three months. Many methods of using radium had been devised, but Mr. Pinch's usual practice now was to use several tubes buried in the growth for six hours. On the rare occasions on which he saw operable cases he invariably passed them on to a surgeon, and, in his opinion, there was very little difference between the results of excision by the knife and by diathermy.

The Need for Radical Measures.

Mr. G. **GORDON-TAYLOR** agreed that the results of operation for cancer of the tongue were appalling. It had been said that the surgery of cancer was the surgery of the lymphatics, but it was not sufficiently realised that the lymphatics of the living subject differed from those described by anatomists, who obtained their information by the injection of the lymphatics in the dead subject. He had been driven by his previous results to perform more and more radical operations for cancer of the tongue and now performed a bilateral "block dissection" followed at a later period by the removal of the tongue by diathermy. He considered that this operation, which he had only been practising for a few years, already showed better results than those of the more limited operations he had formerly performed. For, of the cases he had operated on before 1914 all but one had recurrence within 12 months, whereas the larger operation had already enabled several patients to survive for three years. He did not hesitate to remove portions of the jaw if it were involved, and the operation he performed not infrequently resulted temporarily in considerable œdema of the face, which he regarded in the same light as the œdema of the arm following operation for cancer of the breast as showing a satisfactory removal of the lymphatics.

Mr. A. **EDMUNDS** inquired whether it was not generally observed that cancer of the tongue was much less prevalent amongst the well-to-do classes whose mouths were carefully tended. He also pointed out that second attacks of cancer in the tongue occasionally occurred, and gave one instance. As regards the preliminary treatment of the mouth, he suggested that it was preferable to have the teeth cleaned up rather than extracted, for extraction often left troublesome sepsis in the sockets. Nothing had done more to improve the operative treatment than the introduction of intratracheal anæsthesia, which he now invariably employed. When it was impossible to pass a tube at the beginning of the operation it could still be passed at a later period, when it was most useful. Although he feared that when extensive glandular involvement was present operation was almost hopeless, he still performed an extensive operation in the neck, and removed the tongue about ten days later. He did not ligature the lingual artery at the first operation. Good access to the tongue was imperative, and to obtain this he did not hesitate to split the cheek or to divide the jaw when necessary. It was his practice to sacrifice as little mucosa as possible, and to suture the edges of the wound in the mouth, where he obtained primary union owing to the frequent use of chloramine-T mouth washes.

Mr. H. S. **CLOGG** pointed out that recurrence after operation for cancer of the tongue was only rarely in the mouth. He had therefore given a trial to "block dissection," but without any improvement in his results, for recurrence took place in the neck under the upper part of the sterno-mastoid muscle in the region of the apex of the mastoid process and the posterior belly of the digastric. He now made a special attack upon this area by dividing the sterno-mastoid close to its upper attachment, although he could not yet claim any improvement in results from this procedure. He now regarded the outlook as hopeless, and the cases inoperable if the glands were adherent to muscle or fasciæ, or if they were cystic.

Mr. **CECIL ROWNTREE** said that the incidence of this disease was undoubtedly much less in the wealthy classes than in hospital patients. He agreed that fresh tumours occasionally occurred, and he instanced a case in which he had upon three occasions performed a local excision of an early cancer from the tongue of one patient. His experience of this disease led him to regard such cases as suitable only for a palliative operation unless they were very early. When the disease was well established he was content with the removal of as much tissue as possible near the mouth in order to prevent recurrence within that cavity. Only when the case was very early did he perform an elaborate operation involving an extensive dissection of the neck. In the employment of radium for the primary growth, he considered it important to bring the emanations into the closest possible contact with the growth, and he had recently induced a patient to keep four "needles" in the growth for 24 hours.

Mr. W. G. **SPENCER** pleaded for earlier recognition of the disease by the public and the general practitioner, and pointed out that the patient's resistance to squamous-celled carcinoma was very variable, and had a greater influence on the results of operation than the type of operation performed. While he agreed that the results were on the whole depressing, he stated that several of Butlin's cases were still alive. He thought that the division of the mylohyoid advocated by Mr. Berry was unnecessary and led to considerable discomfort from the dribbling of saliva. He performed a modified Kocher dissection with special attention to the three angles of the wound.

Dr. A. **LAPTHORN SMITH** believed that with proper attention to the teeth of the hospital classes cancer of the tongue would become a rare disease.

Reply.

Mr. **BERRY**, in reply, said he could not understand why a dissection of the glands should be performed before a removal of the primary growth, and he inquired what happened under these circumstances to disseminated cancer cells during the interval between the two operations. He did not know what his results had been, although the fact that he rarely saw patients after operation led him to suppose that the results were bad compared with those of cancer in other situations. His most successful result had been in the case of a medical student in whom a small growth had been present for six weeks, and who exhibited no secondary glands.

CARDIFF MEDICAL SOCIETY.

A MEETING of this Society was held on Feb. 13th, Prof. E. J. **MACLEAN**, the President, being in the chair.

Dr. **IVOR J. DAVIES** read a paper on

Subacute Infective Endocarditis,

based upon a report of eight cases. The term was applied to cases of old endocarditis with an added subacute infective process of streptococcal origin. There had been an apparent increase in the disease recently. Clinical data were submitted in support of Poynton's view that no hard-and-fast line could be drawn between simple endocarditis and infective endocarditis. In four cases an arthritis of the larger joints was present, indistinguishable from that of subacute rheumatism. In one of these cases the post-mortem appearances resembled those of simple endocarditis, except that there was an extension of the morbid process to the wall of the left auricle. The clinical picture was described as, briefly, that of a case of V.D.H., usually aortic in the case of ex-Service men, with certain general signs and symptoms added to those of the mechanical cardiac disability. These were grouped under two heads: (1) toxic, (2) embolic. Enlargement of the spleen was perhaps the most valuable early sign. Clubbing of the fingers, too, occurred early in the disease. The embolic signs shown by the eight cases included petechiæ, a papular and nodular eruption, mycotic aneurysms of the femoral and brachial arteries, intermittent albuminuria, and hæmaturia. The duration varied from three months to two years and was 12 months on an average.

Vaccine and serum therapy, as in other forms of septicæmia, appeared to be the most promising line of treatment. The termination was from heart failure, except in two cases in which acute uræmia was the final event. Blood culture might show the streptococcus, and if negative from venupuncture, then a little blood could be withdrawn from the spleen for cultural examination.

Dr. R. **Prichard** stated that in most of his cases of subacute infective endocarditis there had been an antecedent history of rheumatism. He was of opinion that an infection of intestinal origin played an important part in the subsequent development of the condition; he had frequently noted the presence of tympanitis and general atony of the bowel, and he had succeeded in obtaining temporary improvement of the cardiac state following the administration of intestinal antiseptics. In one case, which he quoted, the ætiological factor (pyorrhœa alveolaris) was strikingly demonstrated; removal of the teeth was followed by relief of the valvular symptoms, and the man's condition so improved that at the end of six months he was sent back fit for light duty.

The **President** asked if the condition occurred more frequently in one sex than the other, and if auricular fibrillation had been present in any of the cases.

Dr. H. A. **Haig's** contribution to the discussion was based on the post-mortem examination of 30 cases seen at a pensions hospital during 1920–21. The majority showed a streptococcal infection of either the aortic valve or the aortic and mitral valves together. In a few cases *S. hæmolyticus* had been proved by blood-culture to be present during life. Regarding antecedent conditions in the heart valves, especially the aortic, the question of a specific history was raised. Throughout the series of cases the kidneys were the seat of lesions referable, he considered, to the slowly-acting toxæmia directly connected with the infective process. There was a possibility, he agreed, that some of the changes were due to an antecedent attack of trench nephritis; on the other hand, the evidence of recent mischief pointed directly to the involvement of the kidneys in the general process. He mentioned the further possibility of war wounds having acted as portals of entry for the systemic streptococcal invasion.

Dr. **Herbert Evans** related a case of subacute infective endocarditis where he had been able, also, to trace the secondary involvement of the aortic valve from the mitral. He quoted Cotton to the effect that the earliest manifestations of petechiæ were to be noted under the finger-nails and in the sub-palpebral onjunctiva.

Dr. **Davies**, in reply, agreed with Dr. Prichard with regard to the value of treating any coexisting alimentary intoxication. The condition was equally common in both sexes, and auricular fibrillation was an infrequent event. He disagreed with Dr. Haig regarding the renal lesions, being of opinion that diffuse nephritis occurred in acute infective endocarditis rather than in the subacute variety. There was no reason for believing that war wounds played any prominent part in the ætiology of the latter process.

A Case for Diagnosis.

Dr. H. **Sheasby** showed a case for diagnosis of a boy, 8½ years old, with a large swelling in the right thigh, which first appeared at the age of 2½ years on the outer surface of the middle third of the thigh and had since got gradually bigger. There was slight pain when the leg was fully flexed. For three months it had been treated as a tuberculous lesion, but aspiration was negative and a skiagram showed no involvement of the femur.—The general consensus of opinion of the members present was that the condition was due to the presence of a lipoma underlying the quadriceps extensor.

The Bactericidal Action of Tears.

Mr. J. W. **Tudor Thomas** gave a demonstration, illustrated by cultures, of the bactericidal action of tears. Basing his work on the technique of Fleming, with various modifications, he showed that both fresh and boiled tears killed young cultures of *Sarcina flava* in dilutions of 1 : 1000. He further showed that heating tears to dryness and redissolving the residue had no effect on their bactericidal properties. Undiluted tears killed *Staphylococcus albus* and inhibited its growth in dilutions of 1 : 40. No bactericidal action was noted in the case of *Bacillus coli*, *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Bacillus pyocyaneus*. It was suggested that in estimating the sterility or otherwise of the conjunctiva the material obtained should be diluted appropriately in order to neutralise its bactericidal action; the latter would appear to be either organic in nature or closely bound up with the albumin molecule in the tears. It was improbable that it was in the nature of an enzyme, since its action remained after boiling.

MIDLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A meeting of this Society was held at the Royal Infirmary, Leicester, on Feb. 13th, Dr. C. E. **Purslow**, the President, being in the chair.

Exhibition of Cases and Specimens.

Dr. H. T. **Hicks** (Derby) showed microphotographs from a case of endometrioma of the ovary. The patient, a single woman of 34, gave a history of three years' severe dysmenorrhœa and menorrhagia. A fixed tender mass was palpable in the pouch of Douglas, and the uterus was enlarged and hard. The left ovary was found fixed in the pouch by dense adhesions, and the right ovary similarly adherent to the broad ligament, whilst a small tumour enlarged the fundus uteri. Both ovaries contained multiple "tarry" cysts. The microphotographs produced showed numerous glandular spaces in the ovarian stroma lined by cylindrical epithelium. Dr. Hicks discussed the theories of the pathology and ætiology of these cysts, and considered that the most likely explanation was endometrial metastases, though the cause of the migration of the endometrium remained obscure.

Dr. T. C. **Clare** (Leicester) reported three cases of adenomyoma of the recto-vaginal septum. 1. A hard, round mass projecting into the rectum without involvement of the mucous membrane, associated with severe dysmenorrhœa and constipation. Uterus enlarged by fibroids. Pan-hysterectomy was performed. Sections of the tumour from the recto-vaginal septum showed (1) gland acini lined by a single layer of cells resembling uterine cells; (2) stroma, having the appearance in parts of fibromyoma. 2. A small, hard tumour felt in the recto-vaginal septum, and projecting slightly into the posterior fornix. There was long-standing dysmenorrhœa. The tumour—removed by incision into posterior fornix—showed gland acini and fibromyomatous stroma. 3. Symptoms of severe dysmenorrhœa and menorrhagia having been shown, a small tumour was felt behind the cervix, and was removed through a vaginal incision. The tumour contained a single large cyst lined by flattened epithelium, and embedded in a fibromyomatous stroma.

Dr. C. D. **Lochrane** (Derby) reported: 1. A case of adenomyoma of the recto-vaginal septum, showing decidual reaction during normal pregnancy. The patient complained of feeling something obstructing the rectum during defæcation. A multi-lobulated tumour was felt in the recto-vaginal septum, not palpably connected with the uterus, and encroaching on the lumen of the bowel. 2. A case of adenomyoma of the uterus in pregnancy, showing decidual reaction. 3. During Cæsarean section in a primipara of 42, a tumour, the size of a billiard ball, was found in the posterior wall of the uterus. Hysterectomy was performed. No symptoms except dysmenorrhœa had been manifest. These cases were illustrated by slides. Dr. Lochrane discussed the ætiology of these tumours.

Dr. **Lochrane** also showed a specimen of carcinoma of the vulva following leucoplakia. When the case was first seen there was no evidence of malignant change, but when seen after X ray treatment there was an obvious epithelioma with glandular involvement.

Mr. **FURNEAUX JORDAN** commented on the disappointing results of X ray in the treatment of leucoplakia and carcinoma of the vulva.

Mr. **CECIL MARRIOTT** (Leicester) opened a discussion on the

Treatment of Full-term Ectopic Gestation.

He referred to a meeting of the Section of Obstetrics and Gynæcology, Royal Society of Medicine, held in 1919, when the late Mr. Gordon Ley produced notes of 100 collected cases, from which he showed that the maternal mortality was high in cases of early operation, whilst there was risk of infection of the sac if left for long after full term. The mortality amongst babies delivered at the time of false labour was low, and many of these babies (50 per cent.) presented various degrees of deformity. Treatment resolved itself into early or late operation. In early operation the maternal risk from hæmorrhage was very great, and though, in suitable cases, after primary ligature of all big vessels the sac and placenta might be removed without excessive bleeding, it was probably wiser to marsupialise the sac and leave the placenta to natural absorption. In cases where no effort was made to save the child operation should be delayed for at least three months, by which time bleeding would be greatly lessened and the operative risks small. Mr. Marriott reported the details of a case operated on by him on these lines three months after spurious labour.

The **PRESIDENT** and Mr. **JORDAN** took part in the discussion, referring to one of the earliest cases successfully operated on at term—by the late Prof. Taylor. Mr. Jordan also reported two cases; one operated on two years after false labour, in which the sac contained the fœtal bones and some dark brown fluid, and the other seen two months after term, which presented no operative difficulties.

Dr. **HICKS** mentioned a recent case in which he delivered a living but deformed child. Both walls of the uterus and the placenta were encountered and incised before the sac was opened. There was brisk hæmorrhage, dealt with by marsupialisation of the sac and plugging. In view of the formidable nature of the operation at term Dr. Hicks strongly favoured late operation.

Dr. **CLARE** mentioned a case operated on two weeks after labour, in which severe hæmorrhage was encountered, though no attempt was made to separate the sac or placenta. He considered a considerably longer interval necessary before operation.

Dr. **LOCHRANE** reported a case operated on 18 months after labour. The placental attachment was in the Fallopian tube, and removal presented no difficulties.

ABERDEEN ROYAL INFIRMARY.—The 138th annual report states that during the year 1922 the average number of occupied beds was 269, being 20 more than in the previous year, while the increase in the number of in-patients was 134, there being 3936 admissions. There were 14,401 out-patients treated, in all 18,337 patients for the year; 2341 operations on in-patients were performed, and at the end of December the waiting list numbered 269, exactly the number of beds occupied for the year. The infirmary has now the benefit of the radium lent by the Medical Research Council, and Dr. John Cruickshank, research lecturer in malignant diseases, Aberdeen University, has been appointed director of radium therapy and research, with Dr. Douglas W. Berry as his assistant. The work will be carried on under the supervision of a local radium committee, consisting of members of the honorary medical staff of the infirmary. The average cost per occupied bed was £104 11*s.* 7*d.*, compared with £124 5*s.* 2*d.* in 1921, and the average cost of each in-patient treated was £7 2*s.* 11*d.*, against £8 2*s.* 9*d.* in 1921. There was an extraordinary income of £2396, which reduced the deficit for the year to £45, as against £741 in 1921. During the year 434 patients were treated in the convalescent hospital.

Reviews and Notices of Books.

ORIGIN AND EVOLUTION OF THE HUMAN DENTITION.

By WM. K. GREGORY, Ph.D., Associate Professor of Vertebrate Palæontology, Columbia University; Curator of the Department of Comparative Anatomy, American Museum of Natural History. Baltimore: Williams and Wilkins Company. 1922. Pp. 548.

IT is some 40 years since Prof. E. D. Cope advanced the view that derived the higher types of molar teeth from a tritubercular ancestry. Even if he had done nothing else, Prof. Gregory would have accomplished a good thing in putting clearly before the non-specialist in odontology the essential difference between this view and the Cope-Osborn hypothesis, which attempted to derive trituberculate from triconodont dentition. The repeated attacks on this hypothesis, and its apparent failure to hold its ground, do not in any way weaken or affect the great value of the first theory: it is well that the two be clearly separated. The Purbeck spalacotheres, foundation-stones for the Cope-Osborn "rotation" hypothesis, seemed to lend themselves more easily to explanation on this view than on others. It came into line with more primitive triconodont dentition. Enormous collections of material have been accumulating for many years in the American museums, and of these Prof. Gregory takes toll to some purpose. On this question of the derivation of the tritubercular type, for example, he is able to show the coexistence of this true type with true triconodont patterns in the Stonesfield slate, thus throwing the question back much further, and removing the spalacotheres from the discussion. Yet the path of progress that led to the earliest tritubercular tooth is still unknown, for *Karoomys browni* seems but a poor guide to it, and we doubt whether the spalacotheres may not represent a persistent primitive stage in their dentition, the more primitive animals having derived their trituberculy on parallel lines, while the evidence for the process is at present unknown.

But the author of this book has done much more than clear away the confusion surrounding the theories: he has given us an authoritative work on a subject which might easily have been wearying, but which he has invested with a compelling fascination. He goes to palæontology for evolutionary evidence, and avoids in this way many of the snares set for the feet of those who labour among modern forms of life. The volume ranges from the primitive Silurian and Devonian sharks to the highest points of the evolutionary tree. Prof. Gregory thinks it probable that the paraconid, metaconid, and entoconid arose in their positions on the slope of the protoconid, and not from any circumduction of triconodont cusps, and looks on the Cope-Osborn hypothesis as not supported by the earliest known trituberculates. He is, however, as is well known, an ardent supporter of Cope's tritubercular theory. He considers the new-world platyrrhines as quite removed from the evolutionary line of the old-world series, and concludes that the mid-tertiary anthropoids lie in or near the line of human ascent—a conclusion with which, we imagine, some will find it hard to agree. Finally, he advances the opinion that man is to be regarded as an offshoot, in late tertiary times, of the Dryopithecus-Sivapithecus group, or some closely related genus.

Many biologists lay less stress than their predecessors on details of dentition, but we have no hesitation in saying that, whatever their views on the matter, this book should be in their libraries. It is, and will be for many years, a standard work on its subject and a necessity for every student of odontology. It is profusely illustrated, well printed, and produced.

Duff House Papers.

Vol. I. Edited by Edmund I. Spriggs, M.D., F.R.C.P., Physician to Duff House. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 387. 30*s.*

Dr. E. I. Spriggs and his assistants take a legitimate pride in their hospital, and express that sentiment here. In addition to the physicians and ex-physicians of the staff, the contributors include surgeons who have worked with them, chemists and radiographers, the diet Sister, and the head gardener to the establishment. But it would be conveying a false impression to say that the work is merely a handbook showing the nature of the hospital, for the collection of papers, reprinted in the main from leading medical journals, contains contributions to our knowledge of alimentary disease as important as any that have appeared during the last ten years. The monographs from the editor and Mr. O. A. Marxer dealing with the radiography of the vermiform appendix, with the failures of gastro-enterostomy, and with diverticulitis deserve wider attention than they could obtain in casual publications, while that by Dr. Dennison Pickering on the blood-sugar in diabetes, Dr. Philip Conran's account of meat diet in sprue, and the editor's essay on sulphæmoglobinæmia contain data of the greatest value. A well illustrated account of the radiographic routine at Duff House, written by Mr. Marxer, may be taken as an epitome of modern special practice.

The inclusion in the volume of the pamphlet entitled "The Patient's Manual of Diabetes" is puzzling, for there can hardly be a public to whom this and the rest of the book can make an equal appeal.

Röntgentherapeutisches Hilfsbuch.

Second edition. By Dr. Robert Lenk, Assistent am Zentralröntgenlabatorium des allgemeinen Krankenhauses in Wien. Berlin: Julius Springer. 1922. Pp. 72. 2*s.*

This small book has been written in order to help specialists in other branches of medicine and general practitioners to obtain a grasp of the principles and the main points in X ray treatment. It is divided into two portions; the first part touches lightly on the general problems of ray treatment, while the second deals with a number of diseases in alphabetical order. Practically no reference is made to the technical side of X ray apparatus.

The general section deals with the usual subjects such as the action of X rays on tissues, the prognosis of diseases, the duration of treatment, the course of diseases under the influence of rays, the immediate effects of X rays, the X ray reaction, and late changes following irradiation. In this last respect the late necroses following from months to a year after treatment by irradiation are mentioned. These have fairly often been noted on the continent, particularly following the massive doses of deep therapy; attention is also drawn to laryngitis following X ray treatment of tumours of the neck, though no mention is made of the still more serious condition which has occurred in Germany—namely, necrosis of the larynx. Accessory treatments and contra-indications are largely reserved for the special section of the volume. The last section of the first half of the book explains the author's method of writing a formula for treatment in different cases. He draws attention to the difficulty of providing a generally applicable formula owing to the variations in treatment necessary in different cases, the knowledge of which can come only from experience.

The second part of the book deals with a rather bewildering variety of diseases, showing the Mid-European tendency to claim a very wide sphere of usefulness for X rays. The treatment of skin diseases as a whole calls for no comment, but the claim that relief from pain and improvement follow treatment in angina pectoris, asthma, gall-bladder pain, badly working gastro-enterostomies, and osteomalacia should be received with some reserve. In the passage on the X ray treatment of hypertrichosis the note "Kontraindikationen—Keine" would permit the unskilled to set out on the treatment of this condition with far too light a heart. Lipomata are reported to shrink under ray treatment, while chilblains are said to be cured by it, but no mention of relapse or failure to respond is made. In the treatment of malignant tumours the massive dosage to obtain the "knock-out blow" is not apparently used, but a preliminary "try-out" dose is given, followed by a prolonged course of treatment. Combined radium and X ray treatment is recommended, but no help is given in respect to the exact combination of dosage. Radium is recommended for the treatment of cancer in the various orifices of the body.

The book is a useful aid to X ray treatment, but it is doubtful if many English practitioners would feel adequately rewarded for the trouble taken in reading it through.

Diseases of the Skin.

Ninth edition. By Henry W. Stelwagon, M.D., Ph.D., late Professor of Dermatology, Jefferson Medical College. With the assistance of Henry K. Gaskill, M.D., Dermatologist to the Philadelphia General Hospital. London and Philadelphia: W. B. Saunders Company. Pp. 1313. 50*s.*

Prof. Stelwagon's death occurred while the ninth edition of his text-book was in course of preparation, and Dr. Gaskill has completed the task of revision, making use as far as possible of the notes and abstracts left by the author. The book is so well known to dermatologists that a detailed exposition of its merits is hardly necessary. Each edition through which it has passed has been remarkable, not only for the full and carefully compiled accounts of the ætiology, symptomatology, and treatment of all the recognised diseases of the skin, but still more for the wealth of references, with comments, to original articles. At the same time it is not merely a compilation of other people's views and writings, but contains the author's personal experience, and several valuable suggestions in the sections on treatment. It will remain, however, essentially a work of reference for professed dermatologists, since it is far too bulky and detailed for the average practitioner or the student of general medicine. As a single volume text-book of dermatology it holds a notable position, and is a monument to the patient industry of its author. It is to be hoped that Dr. Gaskill will be able to make himself responsible for the preparation of future editions.

Diseases of the Heart.

Second edition. By John Cowan, D.Sc., M.D., F.R.F.P.S., Physician to the Royal Infirmary, Glasgow; and W. T. Ritchie, O.B.E., M.D., F.R.C.P.E., F.R.S.E., Physician to the Royal Infirmary, Edinburgh. With a chapter on "The Ocular Manifestations of Arterial Disease," by Arthur J. Ballantyne, M.D., F.R.F.P.S. London: Edward Arnold and Co. 1922. Pp. 605. 30*s.*

In recent years much of the progress in our knowledge of the cardiac mechanism has been the outcome of work along highly specialised lines. The developments of electrocardiography, even the simpler forms of graphic records obtained by means of the polygraph, and such closely allied subjects as the reaction of the blood in relation to dyspnœa, are so different from the teaching of 20 years ago as to prove somewhat bewildering to those who have neither the time nor the opportunity for keeping touch with modern physiology. Consequently, in the minds of practitioners and even of general physicians there has arisen a tendency to divide cardiology into two compartments, the old and the new, with a not unnatural danger of underrating the importance of either the one or the other. Writers have been confronted by the same difficulty, and in attempting to embrace the whole subject of cardiology have generally been content to make their pudding from the old recipe of their predecessors, and to serve up the newer work separately in the form of a sauce to be taken or left according to taste.

For this reason perhaps more than for any other Drs. Cowan and Ritchie are to be congratulated on having produced an extremely palatable dish in which sauce and pudding have been intimately blended to their mutual advantage. Their book is not merely a comprehensive exposition of the old and the new cardiology: it is a work in which the two have been welded into one, the new facts having been so assimilated as to become an integral part of the older teaching. The introductory chapters are followed by an account of disorders of the five primary cardiac functions. Next come auricular flutter, fibrillation, and nodal rhythm. Acute endocarditis, chronic valvular disease, heart failure, and angina are dealt with in detail. D.A.H., pericarditis, and congenital lesions complete the diseases of the heart, and the remaining chapters are devoted to diseases of the arteries, including aneurysm, together with a description by Dr. A. J. Ballantyne of the ocular manifestations of arterial disease. The book is well illustrated throughout by a large collection of drawings, microphotographs, electrocardiograms and radiograms. The present conception of "D.A.H." and functional cardiac murmurs receives critical consideration. These subjects have recently attracted much attention owing to the exceptional opportunities afforded by the war for investigating large numbers of cases, and our ideas concerning the significance of certain symptoms and physical signs have become profoundly modified.

There are one or two aspects of cardiology which might with advantage be dealt with more fully in a future edition—for example, the work of Eggleston and others in America on the treatment of auricular fibrillation with massive doses of digitalis; the diagnosis of the common subacute type of bacterial endocarditis; and the differential diagnosis of true from pseudo angina pectoris. All of these are subjects in which the practitioner looks for guidance. Especially attractive are the chapters dealing with the various derangements of cardiac function. The account of these disorders is admirably clear both from the point of view of diagnosis and of prognosis. The practical problems of treatment are fully considered and the importance of prolonged rest in acute endocarditis is duly emphasised. A comprehensive work such as this must necessarily contain a large number of references to original papers and publications. The authors have, however, succeeded in giving to it a strongly personal character by basing their arguments as far as possible on illustrative cases drawn from their own experience.

The lucid and practical character of the book will appeal to the student and practitioner, while its completeness will render it of real value to those who are especially interested in diseases of the heart.

INJURY, RECOVERY, AND DEATH.

In Relation to Conductivity and Permeability. By W. J. V. OSTERHOUT, Ph.D. London and Philadelphia: J. B. Lippincott Company. 1922. With 96 text-figures. Pp. 259. 10*s.* 6*d.*

Dr. Osterhout, professor of botany in Harvard University and one of the editors of the *Journal of General Physiology*, is, along with Dr. J. Loeb and Prof. T. H. Morgan, responsible for the "Monographs on Experimental Biology" of which this volume is one. The general preface to the series says, "Experimental Biology and General Physiology are one and the same science, by method as well as by contents, since both aim at explaining life from the physico-chemical constitution of living matter"; and the individual preface avows that "this volume endeavours to treat certain aspects of biology according to the spirit and methods of the exact sciences." From which quotations the reader will know what to expect. The author found some time ago that, by cutting discs out of the fleshy leaves of the seaweed *Laminaria* and putting them together into a column of which he could fairly easily measure the electrical resistance, he was provided with a technique which would enable him to make a great number of "exact" measurements under an endless variety of conditions. When this representation of an organism is treated with poisonous agents the conductivity increases, sometimes after a preliminary fall, roughly in proportion to the degree of injury which it is reasonable to assume the particular poison would be likely to inflict on it. If the injury is slight and the poisonous agent then removed, conductivity partly or wholly returns to its normal level. If the poisonous solution with which the pieces of leaf are treated is strong enough, conductivity progressively increases and the tissue passes beyond the point where recovery is possible and dies. The book is an account of Prof. Osterhout's researches along this and similar lines, and appears to be a summary of the 53 papers by him which are mentioned in the bibliography. It is in no sense a general discussion of what is known and what has been thought and imagined on the topics of injury, recovery, and death.

With the example of muscle-nerve physiology before us, it would be idle to criticise the author's outlook on what he has decided to call "biology" or his method of approach. "Wiring frogs on to machinery" was jeered at enough in this country until we realised that the instinct of du Bois Reymond, Sanderson, and the other great minds who engaged in that occupation was a sound one, and that the intensive study of the conditions and mode of action of the highly specialised excitable tissues has brought us to general conclusions of the first order not only in general biology (sensu Anglico), but actually in practical medicine. Prof. Osterhout's flair may be as good: we hope so.

SYPHILIS.

Syphilis of the Innocent. A Study of the Social Effects of Syphilis on the Family and the Community. By HARRY C. SOLOMON, B.S., M.D., and MAIDA HERMAN SOLOMON, A.B., B.S. Washington: United States Interdepartmental Social Hygiene Board. 1922. Pp. 240.

THIS book is the result of investigations made by aid of a grant of funds from the U.S. Interdepartmental Social Hygiene Board, and is an attempt to show syphilis in its social aspects. The scheme of the book may be gathered from the section headings: The Individual, The Mate, The Child, The Family, The Community. In Chapter I. two errors of fact have appeared. The discovery of the treponema is dated 1906, and the Wassermann reaction 1909, instead of 1905 and 1906 respectively. In the chapter on the child much has been written in regard to congenital and antenatal infection, but little new light has been shed on old problems. In the chapter on the family we find much interesting matter on the laws of the United States as to examination and certification of people before marriage. The practice evidently is much more extensive in this respect than in this country. The book will be of interest mainly to the lay reader, and contains much valuable propagandist matter.

Syphilis and Syphilis-like Diseases of the Mouth. For Doctors, Dentists, and Students. Third enlarged edition. By Dr. FERD. ZINSSER. Berlin and Vienna: Urban and Schwarzenberg. 1922. With 71 illustrations, of which 54 are coloured. Pp. 153. 12*s.* 6*d.*

THIS book serves an excellent purpose—it brings together a mass of information about syphilis and similar affections of the mouth, which those interested would have to plough through much literature, medical, surgical, and dental, to find. Its greatest feature is its wealth of beautiful illustrations, and the text is concise. This profuse illustration is necessary as it would be difficult for all those in need of such a book to see the cases in all the different clinics where they would present themselves. This third edition is enlarged and revised, and shows some new plates, especially of foot-and-mouth disease. It is an excellent work, and should be perused by every dentist and doctor for his own safety and that of others.

PHYSIOLOGIE NORMALE ET PATHOLOGIQUE DE LA MICTION.

By Dr. GEORGES LEMOINE. Bruxelles: Imprimerie Médicale et Scientifique. 1922. Pp. 102.

THIS monograph comes from a clinician who, in order to understand some of the various problems which confronted him in his work, found himself impelled to make a careful study of the anatomy and physiology of the whole urinary tract and especially of its innervation. He has as a result produced a somewhat curious treatise in that two-thirds of the contents are occupied with a résumé of the anatomy and physiology of the parts concerned and rather less than one-third with the clinical phenomena. But the reader can have no quarrel with this arrangement; it is, in fact, extremely useful to find put together in small compass a complete account of the more recent researches in a subject difficult to understand, and Dr. Lemoine deserves the thanks of clinicians for thus making them readily available.

When he has thus laid the foundation for his clinical studies he is able to present these in a few pages which can be easily followed. He deals in successive sections with incontinence, spasm of the urethra, and retention of urine. He has not perhaps much that is new to say in this field, but he is able to present his facts in a logical fashion. For example, he can give a classification of the varied types of incontinence based on physiological conception. In the actual diagnosis of what he styles "essential incontinence" he appears to attribute considerable importance to measurements of the pressure of fluid contained within the bladder, which he ascertains by the employment of a manometer. To us this appears to be the least convincing part of his work.

The monograph does not claim to present much original work, but it gives a clear and concise account of the present state of our knowledge of the subject of the physiology and pathology of micturition.

JOURNALS.

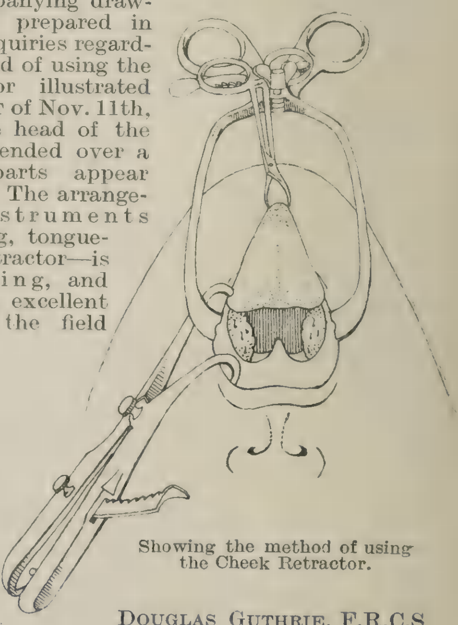
JOURNAL OF INDUSTRIAL HYGIENE.—In the January issue Bishop Harman gives figures showing that out of 480 myopes 53 per cent. of those who were engaged as habitual close eye-workers broke down with visual defects, while of those who were not so engaged only 9·4 per cent. broke down. He found that the tendency to break down increased with the degree of myopia; thus whereas out of 71 close eye-workers whose myopia varied from 3–5 D., 24 sustained visual injury, out of 31 with myopia over 10 D., 24 suffered. He concludes that the risks associated with myopia are heavier if habitual close eye-work is followed, and that the liability to damage is so great that young persons affected with myopia should be prevented from embarking upon such work.—An article of considerable importance, by the late Sheridan Delépine, upon the effects of exposure to arsenic trichloride is completed; it is a good posthumous instance of the careful work of the lamented author. He shows how arsenic trichloride spilt on the skin led to death from acute arsenicism. Special methods of estimating arsenic present in the tissues are described, and the amount found both in workmen and animals exposed to fumes of arsenic trichloride is stated. Aqueous vapour was found to decompose arsenic trichloride, and water-seals are, therefore, suggested to protect vessels whence this poisonous chemical might escape.

In the February issue observations made under the direction of L. Hill upon the comf-thermometer are given; the instrument itself is first described; it is essentially a fresh-air gauge intended to give some measure of the feeling of comfort given by any atmosphere. The observers aimed at obtaining a relation between the comf- and kata-thermometer readings. Diagrams are given showing that in the main readings obtained with the two instruments do in fact vary together. The observers conclude that "the comf" is a reliable instrument for indicating whether the air conditions are satisfactory, so long as certain precautions are taken and the instrument is not used in a fast air-current.—A paper of some moment upon the pharmacology of the phenylenediamines, dealt with by P. J. Hanzlik, is concluded in this number. The writer shows that these chemicals are used extensively in industry and art, and are definitely toxic. The different compounds in the group have a toxicity which varies according to their chemical composition. Certain of them may be absorbed through the unbroken skin; they may also cause dermatitis, or even burns. All these compounds stimulate the circulation and respiration, cause fall of body temperature, tremors, increased reflexes, convulsions, coma, and death. The action was studied step by step experimentally upon animals. Hanzlik considers asthma and respiratory troubles, suffered by workers in the fur-dye industry, to be due directly to the use of para-phenylenediamine; he suggests that workmen should be protected in industries where this chemical is used, and that it should be prohibited as a hair-dye or cosmetic. He holds that these compounds are of no value therapeutically.—This number contains another posthumous article from the pen of Sheridan Delépine, who reports upon two fatalities due to inhaling phosgene. He shows that phosgene does not act as a direct lethal agent, but as a powerful irritant of the air-passages, setting up exudation which obstructs the bronchials, acting in this way much as do nitrous fumes. Death results from plugging of the bronchioles, which prevents air reaching the alveoli. Careful particulars of post-mortem examinations are given.

New Inventions.

A CHEEK RETRACTOR FOR TONSIL OPERATIONS.

THE accompanying drawing has been prepared in response to inquiries regarding the method of using the cheek retractor illustrated in THE LANCET of Nov. 11th, 1922. As the head of the patient is extended over a pillow, the parts appear upside-down. The arrangement of instruments—Waugh's gag, tongue-clip, and retractor—is self-retaining, and secures an excellent exposure of the field of operation in the removal of tonsils by dissection under general anæsthesia. A tongue depressor may also be used, but is rarely required.



Showing the method of using the Cheek Retractor.

THE PSYCHOLOGY OF PUNISHMENT.

A critical spirit in regard to social ideas and institutions has been increasingly active since the war, and, as much for this reason as through the influence of certain *causes célèbres*, a deep interest is now being taken by all men in the problems of crime and the attitude of society towards the criminal. Widespread dissatisfaction has been manifested in certain cases with the accepted methods of legal punishment, and we are not prepared to defend existing penal systems as models of intelligent conception or efficiency when applied to many modern conditions. But it is surprising to observe that, quite apart from any question of the inefficiency of particular methods of penal administration, there should be a considerable development of public scepticism regarding the very principle of punishment, and a growing disposition to impugn the value of any punitive or retributive element at all in the treatment of the criminal. This sceptical tendency might, perhaps, be looked for in the speculations of the mental pathologist whose special line of work makes him acquainted mainly with such cases of crime as are closely related to definite morbid conditions in the criminal; the observer who generalises from instances of this sort will naturally incline to extend to all criminals the impunity from punishment which is regularly accorded to the madman and the idiot. It is not, however, solely amongst alienists that this rejection of the punitive principle has become very vocal of late. In the most unlikely quarters, even in the ranks of the legal profession, doubts are freely expressed as to the justice and expediency of penal sanctions, and one of the most recent and thorough-going statements of the case against punishment comes from the pen of an American lawyer who has had long and varied experience in the criminal courts.

The views set out in Mr. Clarence Darrow's book on Crime: its Cause and Treatment,[1] are lucidly presented. His main thesis is that, since criminal conduct, as, indeed, all conduct, is the inevitable consequence of antecedent conditions in the individual and in his environment, it is futile to attribute moral responsibility to the law-breaker, and that therefore the social reaction against crime should be dissociated from any feeling of reprobation, and should be purged of all punitive elements. On this view, the sane offender is in the same position, as regards responsibility, with the idiot and the madman, not because his anti-social behaviour implies any similar abnormality of organisation, but because the conduct of both sane and insane is governed by the same universal laws. Mr. Darrow is thus on firmer ground than the critics of punishment, who rest their case on those more extravagant doctrines of the Italian criminologists, so effectually refuted in the monumental work of the late Dr. Charles Goring. The weakness of Mr. Darrow's argument is not so much in his initial position, as in the conclusions which he draws from his premises. Even if full assent be given to the determinist doctrine, it does not follow that punishment is unjust and illogical. To repudiate the metaphysical doctrine of free will, and to recognise that human conduct is governed by causation in the same way as other natural phenomena, does not by any means imply that there should be no social reaction against the criminal. This reaction is, itself, simply a procedure of self-defence, a response of the group to conduct which it conceives to be hurtful to its interest and safety; and an emotion of disgust and repulsion with regard to the offender is its natural accompaniment. The social reaction against crime may become morbid by deficiency as well as by excess. The feeling of moral indignation which is awakened by a particularly hideous crime is, in fact, an indication of a healthy state of public opinion, and the fear of awakening such a feeling in the group is, perhaps, even more potent as a deterrent from crime than is the anticipation of material punishment.

Apart from positive evidence of experience, the universal belief in the deterrent value of punishment is in itself in some sort a proof of its efficacy. In the determination of conduct a belief has the force of a reality, and when the average man feels, as he does feel, that legal punishment and the disgrace that attaches to it act as motives that deter him from crime, there is no reason to question their potency. Nor is this view in the least inconsistent with the admission of the legal irresponsibility of the insane. It is not because the acts of the insane are supposed to be more subject to the laws of causation than are the acts of the sane that civilised communities abstain from punishing madmen for their crimes. So far as this more lenient attitude has a rational basis, it is due in part to a recognition of the fact that mental disease abolishes or diminishes the power of reacting to the influences which tend to restrain sane persons from breaking the law, so that to punish the insane criminal is useless from the point of view of deterrence; and it arises in part from the feeling expressed in the old dictum that the madman is sufficiently punished by his madness. That is the explanation of much of the popular emotion which is aroused when borderland criminals escape punishment on dubious pleas of insanity; such offenders, prior to their criminal exploits, have not been liable to the legal disabilities that affect the sufferers from more definite disorder of mind. Society can and does deprive the lunatic of his liberty to guard against his dangerous proclivities; when his madness is recognised he is locked up without waiting until he has committed a criminal act. The borderland criminal, on the other hand, claims to enjoy at once the privileges of sanity and of insanity; he cannot be restrained until he has committed a grave crime, and when he has committed such a crime he cannot be punished.

The real difficulty which this question presents from the point of view of public sentiment and social security has not yet been adequately recognised by those who advocate a wider extension of the plea of insanity in criminal cases. The only way in which it can be met is, as the late Dr. Charles Mercier suggested many years ago, by getting rid of the pedantic notion that there exists a clean-cut and definite line between sanity and insanity, and by admitting the principle of partial responsibility. This principle has not so far found very enthusiastic support either from jurists or from alienists, but it has to some extent been implicitly accepted by the law within recent years, notably in connexion with the criminal responsibility of the alcoholic. The decision that drunkenness may, in certain circumstances, reduce the gravity of an act from murder to manslaughter is a case in point. In other countries the principle of partial responsibility is also gaining ground, and it has, in fact, been fully adopted in the draft proposals for the revision of the Imperial Criminal Law in Germany.[2] The paragraph therein referring to the effect of mental disability on responsibility for crime is as follows :—

---

[1] Crime: its Cause and Treatment. By Clarence Darrow. London: George G. Harrap and Co., Ltd. 1922. Pp. 292. 10*s.* 6*d.*

> "(i.) An accused person is not responsible if at the time he committed the act he was incapable through disorder of consciousness, through mental disease or through weakness of mind, of appreciating the illegality of the act, or of determining his will in conformity with such appreciation.
>
> (ii.) If such capacity was diminished at the time of the act through one of the causes enumerated, the punishment is to be mitigated."

The explanatory memorandum on the proposed law indicates that the mental disorders entailing diminution of responsibility are the same in nature as those which exclude responsibility, but are of lesser degree. It is contemplated that in cases of partial responsibility the offender shall be liable to such punishment as would attach to conviction for a minor degree of the same crime—if the crime, for instance, were murder, the punishment would be that prescribed for attempting or being an accessory to murder. Where judged necessary in the interests of public security, the offender, after completing his mitigated sentence of imprisonment in a penal institution, may be detained under asylum conditions. These proposals are obviously open to criticism on many points, but their affirmation of the principle of partial responsibility is at all events a constructive suggestion, and may well be commended to the notice of the various committees, legal and medical, who are at present engaged in considering the amendment of the English law on the plea of insanity in criminal cases.

◆

THE PROSPECTS OF THE VOLUNTARY HOSPITALS.

THE Voluntary Hospitals Commission, it will be remembered, were appointed in 1921, by Sir ALFRED MOND, then Minister of Health, to be a Commission to administer a Government grant of £500,000 for the voluntary hospitals of Great Britain in accordance with certain terms. The £500,000 was the outcome of a Parliamentary vote, and the terms provided that the amount should be applied in special grants to voluntary hospitals to assist in meeting deficiency in income, but these payments were only to be made on conditions that were approved by the Treasury. Of these conditions the most important one was that, after the urgent cases had been dealt with, the disbursement of the balance of the grant should proceed pro rata against fresh money raised by the charity, or in sight. This condition has been adversely criticised, but, as it was implied in the Parliamentary vote and explicitly embodied in the terms of the appointment of the Voluntary Hospitals Commission, that Commission could only work in accordance with it.

The Commission has now presented an interim report from which we gather that the total amount distributed up to Dec. 31st, 1922, was £373,000, the grant being administered in two groups, one of £225,000 for hospitals in London, the other of £275,000 for the remaining institutions. The grants made already have prevented the closing of beds in many hospitals, and have enabled others to reopen wards that had been shut, and in this way much intolerable strain has been relieved over a large field. The grants have all been made in respect of deficits for maintenance accounts for the year 1921, and inspection of the accounts shows that the Treasury condition of disbursements—namely, that they should be made only where similar sums of fresh money have been raised from voluntary sources—has justified itself. The Commission have found that the condition has proved a valuable incentive to the hospitals to make special efforts, and these have in the aggregate resulted in the receipt by the charities of a larger sum-total than the grant administered by the Commission—in London alone, for example, a combined appeal organised by King Edward's Hospital Fund resulted in obtaining nearly £400,000. A most valuable part of the work of the Commission has been the establishment of Local Voluntary Hospital Committees for England, Wales, and Scotland, London being here excluded, inasmuch as the Council of King Edward's Hospital Fund acts as such a local committee for the metropolis. The duties of these Local Committees consist in collecting information as to district needs ; in organising coöperation between institutions, which may thus be stimulated to the coördination of appeals or to the suitable transfer of patients ; and in inquiring into the coöperative purchase of stores and the adoption of a uniform system of hospital accounts. The Committees are now in being in 42 provincial centres in England, 4 in Wales, 13 in Scotland, and as the personnel comprises representatives of the local authorities, the hospitals, the medical profession, and others directly nominated by the Commission, it will be seen that the work is being done with a full back-ground of knowledge. In some cases, we are told, these bodies have gone beyond the actual list of duties laid down, and have taken the initiative in raising new money from voluntary sources, and it is clear that there is one direction in which they can be especially useful—namely, in the organisation of systematic contributions both from employers and employees in areas where no plan of the sort at present exists. This is a departure of recent date, from which much of the expected success of the voluntary hospital system in the future will come.

Every one who reads the report—and it should be widely perused—will see that the Commission, bringing general and special experience to bear upon what has obviously been close investigation, have found the voluntary system to be full of life and with chances of permanent survival opening up before it. On the whole, hospital incomes have been well maintained, and the deficits in 1921 have proved to be less than was anticipated in Lord CAVE's admirable report.[1] But the members of the Voluntary Hospitals Commission urge a wise caution against a too ready optimism. It can be seen that the margin between income and expenditure, though narrowing, is still wide, and it can be seen also that this has occurred at a time when anything like profuse expenditure has been impossible, but when the needs for it have in some places been very real. The demand for increased accommodation in many hospitals to meet long waiting lists cannot be met without the collection and distribution of very large sums, and unless the hospitality of the hospitals can be rendered both more extensive and more prompt the voluntary system must lie under criticism. The Commission make no recommendation as to the continuance of State assistance after the present grant is exhausted.

THE SOCIABILITY OF ORGANISMS.

A good many bacteriologists have noticed that a loopful of an ordinary culture may fail to start a successful growth if it is planted into a couple of litres of broth when transplantation will be achieved every time into a volume of five or ten cubic centimetres. In practice the difficulty is easily surmounted by using a larger inoculum and the phenomenon does not seem to have been subjected to any detailed analysis. It is possibly due to the presence in nutrient broth of a limited amount of some poisonous substance which is used up by a certain number of organisms; it may be due to large inocula containing more individuals of exceptional vigour and resistance than smaller doses; it may be due to bacteria failing to grow well if they are too widely separated from one another, with the implication that this loneliness is effective because it obstructs some procedure akin to sexual multiplication or because it reduces the concentration of some stimulating substance emanating from the organisms below the limiting level. Some other phenomena are known which seem to be more or less in parallel. Working with the infusorian *Enchelys*, Robertson showed[1] that when two individuals are put together into the same drop of culture medium, not twice, but from four to six or eight times as many individuals are produced in 24 hours as in cultures started with a single individual, and this without any conjugation or encystment. He brings forward evidence, not altogether satisfactory, that this effect is due to the elaboration by *Enchelys* of a stimulating substance out of the autolysed remains of bacteria on which it feeds. Water is said by Drzewina and Bohn [2] to be harmful to *Stentor* if the volume is large, and, as an example of more specific effects, Gould found [3] that the development and maintenance of the male phase in the mollusc *Crepidula* requires the presence in the immediate vicinity of a larger individual, usually transitional or female in sex. Finally, in a very clear series of experiments with the fly *Drosophila* on the influence of density of population on longevity, Pearl and Parker [4] reach the result that the most favourable density is not the minimal density. The average duration of life increased with density of population up to about 40 flies per bottle where it was greatest; it then fell and was equal at densities of 2 and about 90, and thereafter diminished with progressive overcrowding. From these examples it is evident that organisms may exercise a favourable influence on other individuals of the same species, and it is worth while looking for further instances to see if it is a general phenomenon. Human hygiene has taught us very thoroughly that there may be too many people for the best welfare; it is possible that there may also be too few. On the physical side we may question the probability of this, and we are never likely to have any indubitable and unequivocal experience to make sure one way or the other; intellectually and spiritually the value of human companionship will hardly be doubted, and by the influence of the spirit on the flesh this would probably entail some carnal gains as well. Perhaps the basis of our social habit of life will be found by the further analysis of Robertson's phenomenon; in any case loneliness seems to be a generally harmful influence.

Annotations.

"Ne quid nimis."

THE DIRECTOR-GENERAL A.M.S.

It is announced officially that Sir John Goodwin will retire from the position of Director-General A.M.S. as from July 29th next, when he will be succeeded by Sir William B. Leishman. Sir John Goodwin was called to the post he will shortly vacate at a time of grave stress. During the first three years and a half of the war Sir Alfred Keogh had charge of the gigantic developments in the Service entailed upon this country by our bitter struggles upon widely separated fronts, and in circumstances where past experience offered no direct precedents. It was, therefore, a high honour to Sir John Goodwin that he should be selected to succeed Sir Alfred Keogh in his task, and, as we all know, he undertook the huge responsibilities manfully. When at last peace arrived he found himself faced with the vast anxieties bound up with the settling-down processes, and in many and difficult situations he has won high repute among his colleagues, medical and civil, for untiring attention to duties and a very real kindness in their discharge. No chief of the A.M.S. has ever more anxiously guarded the interests of his brother officers, and always with an eye upon the well-being of the soldier.

Sir William Leishman takes over the appointment with credentials which can hardly ever have been possessed in so many directions by any of his predecessors. Assistant Professor of Pathology at the Royal Army Medical School, and later Professor of Pathology at the Royal Army Medical College, Sir William Leishman has served as president of the Society of Tropical Medicine and Hygiene, and as a member of the West Africa Fever Commission and of the Medical and Sanitary Committee of Tropical Africa (Colonial Office). As the discoverer of the causal organism of kala-azar he became F.R.S., while his work in the war is too recent and too well known to need detailing. This is a great record, and Sir John Goodwin may feel happy in handing over the reins to Sir William Leishman with whom he has worked in coöperation for the past 25 years.

THE ÆTIOLOGY AND OPERATIVE TREATMENT OF HALLUX VALGUS.

A long, statistical paper on hallux valgus, by Dr. Torsten Sandelin,[1] of Helsingfors, shows that there is much still to be learnt about the ætiology and treatment of this deformity. He began by investigating its incidence, and after examining some 3200 feet, he came to the conclusion that if a deviation of only 15° is to be accepted as coming within the term hallux valgus, then 80 per cent. of Finnish women may be said to suffer from this condition. Its incidence increases with age; between the ages of 3 and 6 it was only 10 per cent., while at the age of 60 it was 60 per cent. It has generally been assumed that hallux valgus and flat-foot often occur together. So they do, and Dr. Sandelin's statistics show that the greater the lateral displacement of the big toe, the more frequent is its association with flat-foot. But a more common and significant association is that of hallux valgus with flattening of the transverse arch formed by the heads of the metatarsal bones. About half the cases of flattening of this arch were associated with hallux valgus, which was found in barely one-third of the cases in which this arch was retained. In 54 per cent. of all the cases of hallux valgus there was a history of it in the patient's family. But, considering how common the deformity is, this figure can hardly be accepted as convincing evidence of the disease being hereditary or familial. As for the influence of badly fitting boots, it has been assumed that they play an all-important part. It has even been argued that true heredity plays no part, but that pseudo-heredity is of importance in this respect that successive generations in the same family usually wear the same kind of boot! Dr. Sandelin's discussion of the various ætiological possibilities suggests that the genesis of hallux valgus is still very obscure. Turning to operative treatment, he points out that much ingenuity has been shown in devising new operations, and he refers to a certain plastic operation the author of which carries it out in ten different stages. But this inventive fertility has not been accompanied by many persevering attempts to investigate the late results of the various operations. Dr. Sandelin has attempted to fill this gap in our knowledge by examining again the patients operated on for hallux valgus since 1904. He was able to trace 107 patients a year or more after operation. In most cases an operation had been performed on both sides, and the procedure usually adopted was amputation of the head of the first metatarsal bone under local anæsthesia by Hueter's method. Only two of the patients thus treated were dissatisfied with the results, and one of them was a woman, aged 41, who suffered from articular rheumatism and weighed 100 kilos. On the other hand, in none of the cases in which the operation was limited to removal of the bursa and only the most prominent part of the head of the first metatarsal bone (Schede's operation) were the patients entirely relieved of their symptoms, and in no case was the displacement completely corrected. It is, therefore, evident that if operative treatment is to be successful it should be radical.

[1] Finska Läkaresällskapets Handlingar, November–December, 1922.

THE BIOLOGIST'S CONTINUUM.

Modern biology is quite clear that the whole of the live world is a continuous series and that man cannot be sharply separated from the rest. Complete acceptance of this conclusion with all its subsidiary implications in some ways helps in the realisation of God by man and at the same time raises difficulties in the understanding of what that realisation is. The purpose of a little volume[1] recently published, written by a trained biologist and a Quaker, is to discuss some of these problems, and it is carried out with the simple sincerity which we should expect from an author of that connexion. The biologist knows that pain and sin and death are common to the whole live world, and if Mr. Unwin fails, as everyone else has failed, to find a complete answer to the insoluble question of their compatibility with God, he gives a helpful and encouraging discussion of an old problem. The main difficulty, however, which emerges from the biologist's continuum is the position of man in relation to that of the "lower" animals. Two extreme views are possible. In the first, man is unique in having a soul and an existence apart from his morphological body; the future life is reserved for him partly because he was verbally made in God's own image and partly because it is considered that there would not be room in heaven for all live things. In the second, man is the end or an end of a series which includes the whole perceptible world and he cannot therefore be different from its other components in more than a quantitative way. For the first interpretation of the world no one has much to say nowadays; verbal inspiration has gone and the heaven arranged in a Euclidean plan has been replaced by the conception that a good man realises heaven by being a good man and that the hell to which a bad man goes consists of being a bad man. At present the second interpretation receives hardly more support, though the progress of physics suggests the incorporation of what we call the dead world into the biological series. No one seems prepared to go the length of being able to stand before an oak-tree or a butterfly and say *ex animo* "You are as near God as I am." We feel still that it would be in some way a humiliation, forgetting perhaps that the Manichæans long since recognised that they were inconsistent in plucking the leaves of plants for food and carefully preserving their lice from harm. In common with other recent writers on this question, Mr. Unwin takes a middle course. Man does, in fact, differ from other animals in having a soul, but the soul is not a special creation but the product of an evolution which, known in its past history as a physical agent, may well find its future development in spiritual things. It is, therefore, uncertain at what precise point the transition occurs: the difference is quantitative rather than qualitative, and man's "spiritual nature is the development from and the outcome of the essential spirituality of the living organism." Such and such are the topics of the book; we think it will serve its author's purpose to help others to get closer to God.

CHAUVINISM IN MEDICAL TERMINOLOGY.

The influential medical journal issued for 70 years from Munich, where the pure language movement in German literature has long held sway, disclaims the suggestion of the Paris press that this tendency in German medicine is an example of chauvinism. Dr. Spatz—we presume it is he—writes[1] that it was natural to expect that the attempt to delete foreign expressions would excite unfavourable comment. German medical books still contain such terms as *choc en retour, débridement, bruit de pot fêlé, mouches volantes, défense musculaire, formes frustes, petit mal*, and there seems no particular reason why good home-made equivalents should not be found for these and similar terms. Most of them have already been anglicised. Should they be successfully germanicised Dr. Spatz assures us that there is no intention of discarding from German medical literature the names of distinguished foreigners attached to various diseases and objects. German doctors will continue to speak of *Littré's* hernia, of *Dupuytren's* contraction, of *Blaud's* pills, of *Nélaton's* catheter, and of *Addison's* disease. With quick repartee he regrets what he regards as the intentional avoidance of Rontgen's name in France, where the rays are always spoken of as X rays. The attitude of "philologic super-nationalism," he thinks, cannot stand; the sweeping of German medical literature free of foreign crumbs has nothing to do with nationalism. It has already proceeded some way, for at the recent annual meeting of the Society of the German Medical Press, which numbers 156 members, it was agreed to commission the firm of Fleischmann and Reckzeh to publish a pamphlet containing abbreviations for the most commonly used medical technical terms, and a preliminary draft has already been submitted to a committee under the chairmanship of Dr. Spatz.

VARIATIONS IN THE PHYSIOLOGICAL OPTIC DISC.

The study of the normal optic disc is one to which, judging from the majority of text-books on diseases of the eye, comparatively little attention is usually paid by ophthalmologists. In the February number of the *British Journal of Ophthalmology* Mr. Ransom Pickard discusses variations in the normal physiological cup. The common form of cup is caused, as is well known, by the separation of the fibres of the optic nerves as they leave the disc to be distributed to all parts of the retina, and it is generally assumed that, in the absence of either glaucoma or optic atrophy, the size of the cup remains constant from childhood to old age. Mr. Pickard points out what must be common knowledge to all who are accustomed to use the ophthalmoscope, that there are several different types of physiological cup, and further, what to many will be new, that in certain cases which he has examined and re-examined at various intervals of time, their size tends to increase with increasing age. The importance of this observation lies in the possible relation which these normal cups bear to the glaucoma cup. In some cases of chronic glaucoma there is a cup which does not occupy the whole area of the disc and yet is undoubtedly a glaucoma cup. This is a fact which, although it has not found its way into most text-books, is recognised by most ophthalmic surgeons. Mr. Pickard, in his paper, gives diagrams, taken at periods of several months apart from patients who did develop undoubted glaucoma, which strikingly illustrate the fact. In these cases the cause of the enlargement must have been the same as that which produces the typical cup of glaucoma—i.e., an abnormal increase of intra-ocular pressure. Mr. Pickard's argument is that the increase in the size of the cup which he has observed in certain normal cases is also due to intra-ocular pressure, though it may be that this has never risen above the normal. Whilst, however, this may be so, it may also be the fact that in some of these cases, at any rate, an abnormally high intra-ocular pressure may be the cause of the phenomenon. He concludes, therefore, supporting in this what has already been put forward by other writers in the matter of unduly large cups, that the enlargement of the cup in adult life, without symptoms of glaucoma, must be regarded with suspicion, and that such cases require careful watching for the development of glaucoma: whether or not there is any particular type of cup which in the absence of any evidence of increase of size ought to be regarded with similar suspicion is a further point which might be investigated. A form of cup which Mr. Pickard terms "bulbous" is one with an overhanging margin, so that the continuity of the vessels on the periphery of the disc with those lying at the base of the cup on the lamina cribrosa cannot be traced. It is rare for this to be the case round the whole margin of the disc, but it is extremely common for it to be the case as regards about half of it. This fact is hardly consistent with the common explanation of the physiological cup that it is merely the result of the separation of the nerve-fibres. It must either be the result of an anatomical peculiarity or of the intra-ocular pressure acting on the nerve-fibres between the lamina cribrosa and the superficial level of the disc. On the other hand, the appearance is far too common to suggest that there is any close connexion between it and the development of glaucoma.

THE ORIGIN OF GALL-STONES.

NUMEROUS circumstances and influences favour the development of gall-stones, but uncertainty exists as to which of them are contributory in character and which critical. With a view to the elucidation of this subject, Peyton Rous, P. D. McMaster, and G. O. Broun, of the Rockefeller Institute, have made observations on dogs under strictly controlled experimental conditions.[1] It is possible to join a rubber tube to the common bile-duct of a dog and collect the bile under sterile conditions for months. The gall-bladder should be removed at the time of intubation. Dogs thus treated remained in excellent condition. Out of 12 dogs, calculi were found in 6, and in 3 of these the bile had been sterile. The calculi—to begin with multiple and discrete—were found only in the walls of the collecting system of rubber and glass, never in the ducts themselves. Nor did they occur when the rubber or glass tubes remained clear of organic débris (dead cells and mucinoid matter). The early stages of the calculi that had formed on the glass connexions were examined by the microscope. The stones consisted of calcium bilirubinate and calcium carbonate, with a scaffolding of organic material. Cholesterol was not demonstrable in them. The majority had a centre of calcium bilirubinate surrounded by an envelope of crystalline slightly pigmented carbonate; but stones consisting almost wholly of one or other substance were found. The relation between these two salts in the gall-stones of the dog had similarities to that between calcium bilirubinate and cholesterol in human calculi. There is the same tendency in both instances for a nucleus of the pigment material to be overlaid with another substance. These observations seem to show that infection is not the essential factor of cholelithiasis. That it frequently plays the determining rôle is equally certain. This it would seem to do by damaging the duct wall, with result in desquamation—which the sterile cannula did in these experiments—and by lessening the ability of the bile channels to rid themselves of the cell débris. The débris induces or furthers the direct deposition of solids, and may catch and retain potential nuclei for stone formation, in the shape of pigment particles from higher up in the biliary system, which would under ordinary circumstances be voided with the bile.

OCTO-CENTENARY OF ST. BARTHOLOMEW'S HOSPITAL.

THE 800th anniversary of the foundation of St. Bartholomew's Hospital is being celebrated from Tuesday, June 5th, to Thursday, June 7th. On Tuesday, after service at the Priory Church of St. Batholomew-the-Great, delegates will be entertained to luncheon by the governors and staff of the Medical College. In the afternoon the Prince of Wales, as President of the hospital, will receive addresses from the delegates, and in the evening old students of the school will dine together. On Wednesday afternoon a reception will be held at the Royal College of Surgeons of England, the Bartholomew Fair will take place within the hospital precincts, and a banquet will be given to the delegates in the evening. On Thursday, after service at St. Paul's Cathedral, the hospital and medical college will be "at home." During the celebrations an exhibition of historical and scientific interest will be held within the hospital. The gratifying announcement has just been made that the medical college authorities have acquired a block of modern premises in Giltspur-street to be devoted mainly to a new physiology department, which will then have separate laboratories for histology, chemical physiology, and experimental physiology, along with numerous research rooms. The size of the College necessitates and justifies this expansion, for there are at the present time in attendance 690 full-time and 88 part-time students, and the full and part-time entries which in October, 1920, amounted to 243, rose in 1921 to 266 and in 1922 to 286.

SEASONAL PHYSIOLOGICAL PHENOMENA.

THOUGH it is often tacitly admitted that the bodily functions are liable to suffer modifications with the change of the seasons, we have little precise knowledge of the incidence of such changes, and next to none regarding their causation. An example of seasonal variation often seen in the physiological laboratory is the failure of stimulus applied to the vago-sympathetic to arrest the frog's heart during the summer months. This is due to overactivity of the sympathetic fibres in the trunk, and not to inaction of the vagus. The change from the winter to the summer type of response takes place at the mating season, and Cori[1] considers that the response at different seasons has a relation to thyroid activity. It is interesting to note that Seidell and Fenger[2] found that in various mammals the iodine content of the thyroid during the months from June to November is three times as great as from December to May. Reid Hunt[3] found that guinea-pigs were least resistant to the toxic effects of acetonitrile in the winter. It seems reasonable that any effect which the seasons may produce would be due to an effect of change either in the amount of light or in the mean temperature. That light may be an important factor is shown by some recent investigations of Hess and his colleagues in New York. It has been shown by Hess and Unger[4] that exposure to sunlight or to the ultra-violet rays is an important factor in the prevention or cure of rickets, and this important announcement has been followed by the discovery[5] that under the influence of light rich in the actinic rays the inorganic phosphate present in the blood of infants shows a striking increase. This increase is also found to occur naturally during the summer months, when the daylight is far richer in actinic rays. The blood calcium is probably also increased. It seems highly probable that the aggravation of rickets, and the incidence of tetany in the spring, and their improvement in summer are associated with these changes.

DISTEMPER RESEARCH COMMITTEE.

As we have announced, the Medical Research Council are organising the investigation into canine distemper towards which funds will be provided by the "Field" Distemper Council. The researches will be conducted by members of the Council's staff, partly at the National Institute for Medical Research, Hampstead, but more particularly at their new farm laboratory for which a site near London has recently been acquired. As opportunities arise and suitable assistance can be secured, inquiries coördinated with these will be promoted at other centres of work, and the investigations will also be brought into relation with analogous studies in human and animal pathology. The Medical Research Council have appointed the following scientific committee to advise on the subject and to direct the investigations: Sir William B. Leishman, the new Director-General A.M.S.; Mr. J. B. Buxton, F.R.C.V.S.; Captain S. R. Douglas, F.R.S. (National Institute for Medical Research); Prof. F. Hobday; and Dr. C. J. Martin, C.M.G., F.R.S. (Director of the Lister Institute). Sir William Leishman, a member of the Medical Research Council, will act as chairman, and other members may be added to the committee as the programme develops. Communications should be addressed to the Secretary, Distemper Research Committee, 15, York Buildings, Adelphi, W.C. 2.

LETHARGIC ENCEPHALITIS AND PREGNANCY.

In a review of recent literature on lethargic encephalitis by Dr. J. D. Rolleston, in the March number of *Medical Science*, the subject of pregnancy in this disease is discussed. In a paper read before the Medical Society of the Paris Hospitals, Guillain and Gardin, who reported an illustrative case, stated that pregnancy is sometimes normal, or that encephalitis is aggravated by pregnancy, or that premature delivery may occur after death of the fœtus, or that abortion has sometimes to be induced owing to the mother's life being in danger. The fœtus may die in utero or be born in a normal condition, or develop symptoms of encephalitis after birth. With the exception of two cases in which pregnancy occurred in women who already presented the post-encephalitic Parkinsonian syndrome, all the previous cases on record were examples of acute encephalitis occurring in pregnancy. The case reported by Guillain and Gardin was that of a women aged 28, who became pregnant five months after the onset of lethargic encephalitis, when a Parkinsonian syndrome was already well established. Pregnancy was normal, and a healthy child was born at full term, although labour was unusually slow and forceps were required. No change took place in the Parkinsonian syndrome after delivery. In the report on encephalitis lethargica, recently issued by the Ministry of Health, it is stated that in a series of women aged from 17 to 46, who were either pregnant at the time of their illness or developed encephalitis after confinement or within the period of normal lactation, the mortality was nearly 50 per cent.; but after exclusion of seven cases in which pregnancy was a more or less remote antecedent, this figure became reduced to 44 per cent., which represented the general mortality of women between the ages of 20 and 40 who contracted lethargic encephalitis during 1919 and 1920. At a meeting of the Académie de Médecine Mercier, Andrieux, and Bonnaud, of Tours, reported the case of a primipara who, on the twenty-second day of an attack of encephalitis with a myoclonic onset, gave birth to a living child and died on the fortieth day. The child had a slight attack of encephalitis, shown by myoclonic convulsions, when it was a fortnight old but recovered. The case is of interest as showing that the encephalitis, which had commenced three weeks before term and had not been treated, nevertheless did not cause premature delivery or the death of the child. In the subsequent discussion Achard related a case showing that though placental transmission of lethargic encephalitis is possible, it does not invariably occur. His patient was a woman, aged 25, who was delivered of a six months' fœtus a few hours before death, after an illness of 12 days. Histological examination of the mother's brain showed typical lesions of lethargic encephalitis, whereas the brain of the fœtus was normal.

TUBERCULOSIS AMONG NORTH AMERICAN INDIANS.

A Senate committee document with the above title[1] constitutes the report of a committee of the U.S.A. National Tuberculosis Association, officially appointed to investigate tuberculosis among the American aborigines. Its appearance is a reminder of the successful efforts that the United States Indian Medical Service is putting forth to rescue from disappearance the remaining tribes. Even now, we gather, the Commissioner for Indian Affairs would be glad if he had a little more money to spend on health work. But in the present century a considerable advance has been made, as the following comparison shows:—

	1900	*1922*
Hospitals and sanatoriums . .	5 . .	73
Physicians	86 . .	200
Nurses	25 . .	100
Hospital employees . .	15 . .	100
Field matrons	21 . .	75

While health conditions remain far from ideal and much patient educational work is still to be done, it is at least satisfactory to know that for some years births have comfortably outnumbered deaths. The Indian is no longer a vanishing race.

The committee which has just reported was appointed in October, 1921, and consisted of Drs. George M. Kober (chairman), George E. Bushnell, H. E. Dearholt, J. A. Murphy, A. B. Tonkin, and Mr. W. H. Baldwin. The chief medical interest of a report which teems with ethnographical and humanitarian information, is found in its strong argument against special racial susceptibility. An exhaustive inquiry into the writings of explorers and missionaries shows that tuberculosis was certainly known among the Indians as far back as 1635. But all the available evidence suggests that it was not more common among these people than among the whites. The evidence is not, of course, statistical, yet it includes the testimony of physicians who practised for years in Indian communities. After a short contact with the white man, tuberculosis certainly became prevalent, and apparently assumed in many cases an especially virulent form. But this the committee maintains was not due to racial susceptibility but to the imposition of a markedly unfavourable environment. They show how the appropriation by colonists of the most fertile regions destroyed the wild game on which the Indians lived, and reduced the native inhabitants to a state bordering on starvation. The effect of under-nourishment in increasing tuberculosis recently in certain European countries is indicated as a parallel situation. The present poverty and unsatisfactory state of semi-civilisation under which a large proportion of the Indians are living is a continuation of these unfavourable environmental conditions. In 1914, when the death-rate of all American Indians stood at 31 per thousand, nearly one-third of the deaths were due to tuberculosis. The committee recommend the provision of two or three additional sanatoriums and a hospital for hopeless cases, the improvement of salaries for health officials, and the addition of more nurses and field matrons to the staff.

HYDROA VACCINIFORME.

Dr. Francis Eugene Senear and Dr. Harry W. Fink,[1] of the Department of Dermatology and Syphilology of the University of Illinois, Chicago, have collected 78 cases of hydroa vacciniforme seu æstivale from the literature, in addition to two cases which have come under their own observation. In 80 per cent. the sun's rays were regarded as the exciting factor, while in the rest there were additional factors, usually the wind. Hæmatoporphyrinuria, the possible ætiological significance of which was first described by McCall Anderson in 1898, was noted in 14 cases, or in 17·5 per cent., but was recorded as absent in only seven of the others, so that it is probable that in some cases, at least, the presence of hæmatoporphyrinuria accounts for the sensitisation of the individual to the actinic rays, although the origin of the hæmatoporphyrinuria cannot be explained. Hydroa vacciniforme occurs twice as frequently in males as in females, 54 cases in the present series being found in the male, and 26 in the female sex. The disease usually begins in childhood, but a few cases have started in early adult life. As a rule, the eruption ceases or becomes improved at puberty, but it may persist for a few years later. Heredity apparently plays some part, as in five cases the disease was found among brothers and sisters. It has been observed in many countries. A dark complexion is apparently not absolutely protective, as four or five cases have been reported in Italy, and one in South America. No example, however, has yet been recorded in the coloured races. Hydroa is chiefly a disease of the spring and summer months, when the luminosity of the sun's rays is greatest. March and April are the chief months for the onset of the annual attacks, with recurrences during the spring and summer months or sometimes in the autumn and winter. The exposed parts alone are usually involved, the ears, face, and dorsal surfaces of the hands being most frequently affected. Involvement of the cornea was noted in nine cases. The vacciniform type is the characteristic form of eruption, and was present in 53 of the 74 cases in which the character of the eruption was noted, but three other varieties may occur—viz., a superficial papulo-vesicular type, of which there were six cases, an impetiginous type of which there were two, and a severe bullous type of which there were five. The character of the scar formation depends on the type of eruption, varying from a very superficial type to a severe disfiguring form. The eruption is often preceded by sensations of burning or fullness in the affected parts. After appearance of the eruption the patient may suffer from itching and occasionally pain, but frequently does not complain of any symptoms. In a number of cases the onset may be accompanied by general symptoms, such as shivering, nausea, vomiting, malaise, and rise of temperature. Treatment is usually of little avail, but ointments containing quinine or esculin have been of value in some cases.

Sir Arthur Keith, whose health is restored, will deliver the first of a series of six Hunterian Lectures on Man's Posture: Its Evolution and Disorders, at the Royal College of Surgeons of England, on Monday, March 5th, at 5 P.M.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

IX.

THE TREATMENT OF MINOR INJURIES TO THE EYE.

THE only safe attitude to adopt towards a "minor" injury to the eye is to regard it as a possible source of serious danger, resulting in defective vision or even loss of the eye. Thus, a simple abrasion of the cornea may become infected and lead to the formation of an hypopyon ulcer. I have at the present time under my care a man whose left eye was pricked by a thorn. There was a small conjunctival wound about 10 mm. to the temporal side of the limbus. The tension was normal. In the course of a few days he developed vitreous opacities, and the absorption of blood in the wound revealed the presence of a minute perforation of the sclera through which a bead of vitreous was presenting.

Foreign Bodies.

Foreign bodies are frequently blown or otherwise propelled into the eye. In the former case they are most commonly shifted by the predominantly lateral movements of the eye towards the mid-point of the upper lid, where they are caught in the slight groove, known as the sulcus subtarsalis, about 3 mm. from the lid margin. They are easily removed after everting the lid, but this, though a simple procedure, requires some practice. Minute fragments of metal or stone are often propelled on to the cornea, where they become embedded in the epithelium. The commonest are "sparks" off an emery wheel, when grinding tools. These are almost invariably aseptic, but there is never any certainty that virulent pyogenic organisms are absent from the conjunctival sac. The first and most important line of resistance, the epithelium, is broken through, so that these injuries should always be regarded as not improbable sources of serious ulceration. Infection is most liable to occur if a lacrymal mucocele is present, and in such cases is likely to give rise to the most serious form of ulceration —an hypopyon ulcer—owing to the almost invariable presence of virulent pneumococci. The presence of a mucocele is indeed a perpetual menace of such a result, for minute foreign bodies often enter the eye, causing otherwise trifling abrasions, without giving rise to much immediate inconvenience. Particles of stone, and abrasions by leaves of plants and twigs of trees are specially liable to cause hypopyon ulcers, partly due to the fact that the offending agent conveys infection, partly to the lacerated type of abrasion, and partly to the constitutional state of the patient. The evil result most frequently occurs in elderly debilitated patients or alcoholic navvies—in both of which classes the resistance to infection is poor.

In hospital practice, with ideal conditions and skilled assistance, the removal of such foreign bodies is a simple matter. The eye is rendered anæsthetic with 2 per cent. solution of hydrochloride of cocain, the lids are separated by two fingers of the left hand, which also control the eyeball by gentle pressure through the lids, and the foreign body is removed by a spud or discission needle. If very minute, the foreign body may be seen with difficulty. Its position may be indicated by the position of a few dilated conjunctival vessels. These injected vessels are nearest to the site of the foreign body, and as they are radially distributed they act as a pointer to it. Even then the particle may only be visible under good oblique illumination and with the assistance of a magnifying glass or corneal loupe. It may be necessary to use the loupe in removing the foreign body. When the conditions are less favourable it is sometimes possible to remove the foreign body by means of a wisp of cotton-wool, which is less likely to do serious damage to the cornea in the hands of the tyro than the spud or needle.

After removal of the foreign body the eye should be bandaged, and kept clean by frequent irrigation with boric lotion or saline. In most cases the minute abrasion will have healed on the following day, but it should always be inspected, and if there is the slightest grey infiltration of the site the commencement of ulceration is to be feared and appropriately dealt with. In many cases inexpert attempts have been already made to remove the foreign body. Such attempts often fail, and are often made with septic implements. Infiltration has then usually already occurred. The foreign body should be removed with antiseptic precautions, and the eye irrigated with boric lotion or even perchloride of mercury (1 in 10,000). The question arises whether atropin should be instilled. In the case of young people it is a safeguard and free from danger, consequently it should be done in all such cases if there is any doubt; but in the hands of the expert, with careful watching, it is often unnecessary, and it is to be remembered that it will entail absence from work for a week or so. In the case of adults, the instillation of a mydriatic may cause an attack of acute glaucoma. If the infiltration is slight and the conjunctival sac apparently clean, the case may be carefully watched from day to day; but if there is definite ulceration the use of a mydriatic is imperative and the case must be admitted to hospital or kept at home under constant supervision. Similar treatment is indicated in other cases of corneal abrasion in which no foreign body has been retained.

Wounds of the Lids.

Wounds of the lids are treated on general surgical principles, but two points require special emphasis. It has been the lot of most ophthalmic surgeons to meet with cases in which a wound of the lid has been sewn up and quite satisfactorily dealt with, but the fact that the instrument has passed through the lid and perforated the globe has been overlooked. In every case of wound of the lid the eyeball should be very carefully inspected and the tension of the eye gently tested. If the lids are very swollen and ecchymosed, they should be separated by retractors, which allow the lids to be lifted off the globe, so that no undue pressure is exerted on the eye.

In some cases the wound involves the lower canaliculus. In these it is best to examine the nasal lip of the wound and search for the cut end of the canaliculus. A canaliculus knife should be inserted and the canaliculus slit up for a short distance towards the lacrymal sac. The slit should be kept open by passing a dilator or small probe towards the sac on each succeeding day until the edges have become covered with epithelium. If this procedure is not adopted there will be lasting epiphora, which is difficult to treat.

Contusions.

Blows on the eye with fists and other large blunt objects may result in injuries which appear to be trivial, but in all cases a guarded prognosis should be given. Many serious injuries due to this cause have relatively inconspicuous clinical features, and are very liable to be overlooked. A few such may be mentioned—ruptured globe, with or without sub-conjunctival dislocation of the lens; corneal abrasion; hyphæma, traumatic mydriasis, ruptured or retroverted iris, irido-dialysis; luxation or subluxation of the lens, traumatic cataract; vitreous hæmorrhage; rupture of the choroid, detachment of the retina, macular changes, partial avulsion of the optic nerve. As with wounds of the lids, if there is much swelling of the lids they should be separated by retractors and the eyeball thoroughly inspected. If possible the eye should be examined with the ophthalmoscope. Œdema of the retina (commotio retinæ) may be seen and is not necessarily of serious import. Even if no changes are seen in the fundus the outlook should not be regarded too favourably, for in some cases the vision may be normal at first, but slowly deteriorates owing to pigmentary and other changes occurring at the macula.

In all doubtful cases complete rest in bed should be advised. In most cases it is wise to instil a mydriatic, so as to keep the ciliary muscle and iris at rest; but this is contra-indicated in elderly patients if there is any risk of glaucoma. If the lens is known to be partially dislocated I avoid the use of either a mydriatic or a miotic; the former may cause a rise of tension which would not otherwise occur, and is very difficult to combat, the latter irritates the iris and ciliary body.

It is by no means easy to diagnose any injury to the eye as merely trivial or "minor"; and unless the practitioner has devoted special attention to ophthalmic work he will be well advised to call in the aid of an ophthalmic surgeon.

John H. Parsons, F.R.C.S. Eng., D.Sc., F.R.S.,
Surgeon, Royal London Ophthalmic Hospital and Ophthalmic Surgeon, University College Hospital.

Special Articles.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

A meeting of the General Council of this Association was held on Feb. 16th, Sir George H. Makins being in the chair. Mr. Zachary Cope was elected to serve on the Executive Committee in place of Mr. A. E. Webb-Johnson, resigned.

A discussion took place on the recommendations of the General Purposes Subcommittee with regard to a post-graduate school for London, which finally took the following form:—

1. That the post-graduate school in London should be a school of the University.
2. That the post-graduate school should comprise: (*a*) a central administrative office, (*b*) a large general hospital, and (*c*) approved special hospitals.
3. That a dean be appointed to act as the principal officer of the central organisation and to direct medical study.
4. That the general hospital should contain at least 200–300 beds and properly equipped laboratories and lecture and demonstration rooms. The general hospital should be in a central situation and possess facilities for social meetings.
5. That every opportunity should be afforded for lectures or demonstrations by persons other than members of the staff of the post-graduate school and that resident and other appointments should be open to post-graduates.
6. That the general hospital of the school should be one of the existing undergraduate teaching hospitals in a central position and should not take undergraduates.

Mr. H. J. Waring, speaking on behalf of the University of London, said that the University felt strongly the need for a post-graduate school, and urged the Fellowship to get into touch with the University. A central office was necessary, as was the appointment of a dean, but he thought it a mistake to say that the office should be at a general hospital.

The remaining clauses were approved, and it was agreed that the recommendations be sent to the University, with a request that representatives from the Fellowship of Medicine might meet with representatives of the University to discuss their scheme.

It was reported that in accordance with the further recommendations of the General Purposes Subcommittee, a conference had taken place with representatives from the staffs of the non-undergraduate hospitals in London to discuss the best means of furthering the educational objects of the Fellowship; the following resolutions, passed at the conference, had been forwarded to the President for the consideration of the Council:—

1. That in the opinion of this meeting the organisation of post-graduate teaching in London is unsatisfactory. This is due, in part at least, to the fact that the Executive Committee of the Fellowship of Medicine is not representative of post-graduate teachers.
2. That there should be elected on to the Council of the Fellowship of Medicine a representative of each hospital which is doing or is willing to do post-graduate teaching.

3. That the Executive Committee should consist of a representative of each of the hospitals doing post-graduate work with an equal number elected by the Council.

4. That these resolutions be forwarded to the Council of the Fellowship of Medicine, and that this meeting be summoned in one month's time to receive the reply of the Council.

Dr. C. O. Hawthorne, not being in agreement with the method of procedure in calling the conference, moved—

> "That before coming to any decision relative to the resolutions passed by representatives of 27 non-undergraduate hospitals, it is desirable that a deputation from the hospitals should discuss the situation with representatives of the Fellowship of Medicine."

The motion was seconded by Sir Dawson Williams, who suggested that the representatives of the Fellowship of Medicine should be the General Purposes Subcommittee as enlarged in relation to the hospital policy of the Fellowship. The general feeling of the Council was that the question of carrying on for the present until the bigger scheme came into being was very urgent; and in order that no time should be lost, an amendment was moved by Dr. E. Pritchard that resolution No. 2 be adopted and the representatives, as suggested, be constituted members of the Council. The amendment, seconded by Mr. Zachary Cope, was put to the vote and carried. Resolution No. 3 was discussed at length, but its adoption was debarred owing to Clause 8 of the constitution whereby "the Executive Committee shall consist of 30 members." Sir John MacAlister, Dr. G. Blacker, and others favoured the immediate calling of a general meeting of members to revise the constitution, but as this would cause delay, it was felt that some other means must be found to get over the difficulty.

Sir William Hale-White, as chairman of the conference, expressed the desire of the conference to go forward with their scheme, and, urging upon the Council the necessity of immediate action, moved—

> "That after the addition of members on the Council as provided in Clause 2 a meeting of the Council be called within a fortnight."

The motion was seconded by Mr. F. D. Saner and carried unanimously.

Dr. G. H. MacLean, director of the British Division of the American University Union in Europe, referred to the post-graduate activities of Paris, Berlin, and Vienna, and appealed to the Council to do something for London without delay.

OCCUPATIONAL MORTALITY.

The decennial supplements of the Registrar-General, dealing with occupations, are unique and have long been recognised at home and abroad as invaluable. The earliest investigation published related to the year 1851, and with each succeeding censal period the information given has been carefully elaborated. The report now issued deals with 1910–12 [1]; as the data were practically ready for publication at the outbreak of war, the delay which has occurred is notable. Apparently the information even now is only given "in view of many strong representations." The thought that such pressure was needed to save this wonderful series of reports from a breach of continuity gives cause for thinking; it is sad that such pressure was needed at a time when throughout civilised countries, as never before, the science of industrial medicine is receiving attention and being made the object of research. Economy in printing can hardly be pleaded, for previous occupational supplements have sold out and have long been unprocurable—a record not achieved by all Government publications. They certainly were cheap, as the previous one was almost given away for 1*s.* 10*d.*, and the same may be said of a predecessor at 1*s.* 6*d.* The price of the present supplement has been raised to 13*s.* 6*d.*; it contains all the essential data and some important new tables, but, nevertheless, has been bereft of the usual critical and analytical commentary by the medical superintendent which occupied 125 pages in the previous report and formed a much appreciated and often quoted résumé. Gratitude, however, for the moment is uppermost that the report has been issued, and that after all the interests of the community have prevailed over whatever or whoever was the obstacle.

A "Standard Population."

One notable advance has been made: a "standard population" has been fixed at that general male population (71,005), aged 25–64, which produced 1000 deaths at the beginning of the century (1900–02). In previous issues the standard population for each report has been the population which gave 1000 deaths at the period under review. Hence this standard population kept changing, and elaborate calculation was needed before the comparative mortality data of one report could be compared with those of its predecessor. When such comparisons are instituted the mortality experienced is found to have fallen remarkably for every occupation since 1890–92; a few samples from the 132 groups dealt with are given here:—

Comparative Mortality: All Causes.

—	1890–92*	1900–02†	1910–12†	Percentage fall on 1890–92.
Dock labourers.. ..	2114	1481	1127	46·7
Coal heavers	1765	1221	957	45·8
Printers	1267	994	773	39·0
Cotton operatives ..	1318	1114	811	38·5
Brewers	1649	1393	1023	38·0
Medical men	1118	952	693	38·0
Boiler-makers	1162	1032	754	35·1
Commercial travellers ..	1111	988	724	34·8
Brick-makers	857	653	567	34·0
Innkeepers	1899	1781	1265	33·4
Coal-miners	1068	885	727	32·0
All males	1155	1000	790	31·6
Tailors	1144	1027	799	30·0
Clergy	615	524	443	28·0
Shipbuilders	836	817	633	24·3
Farmers..	651	596	495	24·0
Tin-miners	1628	2131	1579	3·0

* Occupied only. † Occupied and retired.

Mortality Groups.

The groups are placed in order according to the extent of the fall in mortality since 1890–92, and the order obtained closely agrees with the height of mortality in 1890–92. The most notable exception is the tin-miners, who owe their excessive mortality to an appalling death-rate from tuberculous silicosis and allied respiratory diseases; the comparative figure for phthisis in this group in 1890–92 was 586, and for other respiratory diseases 435, which remained for 1910–12 at 684 and 315 respectively; the industrial hygienist may be forgiven if he rejoices that this pernicious occupation bids fair to disappear soon from this country; the other marked exceptions are innkeepers and brewers, whose industry appears significantly to have retarded health improvement among its followers. Otherwise there is a clear tendency for those who suffered most in 1890 to have benefited most by 1910. Perhaps the most interesting of the new points brought out comes from the subdivision of the stonemasons group into those employed on sandstone, on granite, and on limestone. By this grouping the claim put forward that those exposed to silica dust (the sandstone group) would be found to suffer in excess from phthisis was put to a crucial test. The result is significant and confirms the claim, for the comparative phthisis mortality in the sandstone group is given as 415, that for the limestone group as 129 and the granite group as 127. Another somewhat similar case of exposure to dust is that of iron-miners; here hematite miners, now given alone, are found with a comparative phthisis mortality of 123, compared with 73 for all iron-miners, or 53 if the mortality of hematite miners be first subtracted from the total group. Again, among coal-miners, with their generally low phthisis mortality, the Nottingham miner has a phthisis figure of 53, compared with 107 for the Lancashire miner.

---

[1] Supplement to the Seventy-fifth Annual Report of the Registrar-General for England and Wales. Part IV.: Mortality of Men in Certain Occupations in the Three Years 1910, 1911, and 1912. Published by H.M. Stationery Office. February, 1923. 13*s.* 6*d.*

The mortality from cancer shows a definite increase, not only among all males from 54 in 1890–92, to 68 in 1900–02, and 78 in 1910–12, but also among most of the occupational groups. The chimney-sweep is an exception, for his comparative cancer figure has fallen from 152 to 107. He no longer heads the list as of old, but has been passed by brewers with a figure of 125, messengers with one of 118, slaters with one of 117, and bronze-workers with one of 108. The whole question of the occurrence of cancer, as exhibited by occupational groups, calls for close investigation. Valvular disease of the heart is another cause of death which increased among all males from 36 in 1900–02 to 42 in 1910–12; here the list is headed by lead-miners (68), lead manufacturers (59), inn-servants (62), hairdressers (58), hair and bristle workers (59), and furriers (57).

There can be no doubt that the data now published will provide material for careful and close investigation, from which interesting results may certainly be expected.

NOTES FROM INDIA.

(From our own Correspondent.)

The Indian Science Congress.

The tenth annual meeting of the Indian Science Congress was held under the auspices of the Asiatic Society of Bengal in Lucknow from Jan. 8th to 13th, with Sir William Marris, Governor of the United Provinces, as patron. Sir M. Visvesvaraya, president, delivered the inaugural address in the Medical College on the evening of Jan. 8th, and the Congress thereafter broke up into its different sections. The Medical Research Section was presided over by Major H. W. Acton, professor of pathology at the School of Tropical Medicine, Calcutta, and 50 papers were read in this section.

A considerable number of the communications were by Indians.

Vitamins: Hydrogen-Ion Concentration.

Colonel R. McCarrison read a paper on the Relationship of Vitamins to Disease, and in the discussion the suggestion was made that symptoms arising in what are known as deficiency diseases might be wholly due to toxic substances produced in the various food grains. This was supported by a number of striking illustrations, especially in connexion with the varieties of rice used in areas where beri-beri is endemic. A paper by Major Acton and Major R. W. Chopra on the Influence of pH on the Activity of Pressor Bases opened up a field for future research, as it demonstrated that the hydrogen-ion concentration affected the action of these bases. Thus, pituitrin was most active at a pH of 6·5. On similar lines was the paper by Major R. Knowles and collaborators on the Relationship of the Intestinal Protozoa of Man to the Hydrogen-ion Concentration of their Environment. After investigation of the pH of stools and intestinal mucosa, it was found that *Entamœba histolytica* in its active motile vegetative and destructive state had an almost constant acid pH of 6·2. Emetine requiring an alkaline pH, before treatment of amœbic dysentery could be effective, it was necessary to alkalinise the intestinal tract by some preliminary salt.

Hookworm Disease.

Dr. J. B. McVail's note on a Suspected Seasonal Variation in the Ovulation Rates of Hookworms was very suggestive, and if his observations are confirmed a considerable amount of energy, time, and money will be saved as regards the treatment of infected populations. Dr. McVail noticed that during the rainy season an increase in the proportion of cases showing large egg counts occurred, and he showed a chart which apparently demonstrates a correlation between rainfall and ovulation. His tentative conclusions were that it was little use treating hookworm cases during the monsoon months, and that the best time to carry out treatment was during the hottest months of April, May, and June.

Lathyrism: Malaria.

The coöperation necessary in the elucidation of some medical problems was well illustrated by the two papers on Lathyrism by Drs. Howard and Simonsen and Captain L. A. P. Anderson, who had carried out the botanical, chemical, analytical, and experimental and clinical parts of the work respectively. Malaria was dealt with in two papers, one by Major Knowles, Major Acton, and Dr. B. Dasgupta, in which spleen puncture findings were discussed, and the other by Major J. A. Sinton on the treatment of malaria with quinine in combination with alkalies. The author demonstrated the better results he had obtained by alkalinising the patient before administration of quinine in a considerable series of unselected cases, and from a clinical point of view the paper would seem to support the work of the Calcutta School on the importance of estimating the pH concentration best suited for alkaloidal action. Colonel W. Glen Liston presented a couple of papers on recent researches on guinea-worm, and Dr. Hamilton Fairley read two very interesting notes on a Possible Serological Classification of Cerceriæ with Special Reference to the Digenetic Trematodes, and a New Serological Test for *Schistosomum spindalis*, and its Practical Value. This test was carried out on the same lines as the Wassermann test, and seemed to give satisfactory results in Dr. Fairley's hands.

Epidemiology.

One of the few papers on epidemiology was read by Major A. J. H. Russell, who described an epidemic of relapsing fever in Madras Presidency. Major F. W. Cragg, in a paper on Relapsing Fever in India, had stated recently that Madras apparently escaped from this infective fever; this has now been shown to be incorrect. Dr. H. McK. Strickland, who has been for some time working at the epidemiology of plague in Bombay Presidency, sent up a paper analysing the results of seven years' epidemics in Belgaum and Dharwar districts; unfortunately this most valuable work had been cut short for financial reasons. Major J. Cunningham and Major J. A. Cruickshank read a paper on animal experiments conducted with the Madras strain of the spirochæte. They found some evidence of the production of an immunity in monkeys inoculated with the strain, as the serum from these animals protected other monkeys when given along with a dose of the spirochætes. Major Cruickshank and Dr. Ramakrishnan presented a paper on Cholera and Cholera-like Vibrios. This paper embodied the findings in a jail epidemic of cholera, and is the first paper published in India as the result of the work of a field bacteriological unit sent out from a headquarters laboratory (in this case the King Institute, Madras). There is little doubt that movable bacteriological units, such as this one, are urgently necessary in every province in India. The unit in Madras, I understand, has already proved of great value on other occasions, and the Presidency is to be congratulated on having initiated a successful scheme.

Congress Exhibition and Handbook.

On the last day of the Congress an exhibition was held, at which diagrams, maps, and models of sanitary inventions were shown. This is the first occasion on which such an exhibition has been held, and it was so successful that it is hoped that it will become a permanent feature of future meetings. Such meetings, moreover, act as a tremendous stimulus to minds which tend to become isolated and cramped, owing to the enormous distances which divide individual workers in India. For the information of members of the Congress a very well got-up handbook had been prepared, to which was added an appendix on the mills of Cawnpore.

Madras, Jan. 25th.

Medical Affairs in Dail Earann: The Local Government Bill.

The discussion on the Local Government (Temporary Provisions) Bill, to which reference was made last week in The Lancet (p. 411), went on during the week. Sir James Craig moved an amendment to the effect that a dispensary doctor or midwife of over 20 years' service, who had become permanently infirm in mind or body, might be allowed to resign on an allowance not exceeding two-thirds of salary, fees, and emoluments. He said it was necessary that young men should be encouraged to go into the service by the prospects of a decent salary or a decent pension. Mr. E. Blythe was not prepared to accept the amendment in its present form. At present a doctor, after ten years' service, was entitled to a pension, and it was possible for the Department to increase the pension in suitable cases. This Bill was only a temporary one; in the Permanent Act, which it was hoped to introduce soon, he would promise to give the proposal put forward full consideration. Sir James Craig thereupon withdrew the amendment.

The Minister's objection, however, to Sir James Craig's amendment appears to be lacking in candour. The clause which Sir James Craig wished to amend would appear to take from medical and other Poor-law officers a statutory right which they have possessed since 1919. Sir James Craig's amendment did not go so far as to protect the existing right in its entirety, but only attempted to preserve it for certain classes of individuals.

Lotteries for Hospitals.

Last week a private Bill was introduced by Dr. Vincent White for the purpose of legalising the holding of lotteries or sweepstakes in aid of hospitals and other charitable institutions. Mr. O'Higgins, Minister for Home Affairs, gave warning that the Bill would meet with his opposition on grounds of the impossibility of closing all the loopholes for corruption and fraud which would be opened. There seems to be doubt in many quarters as to whether it is wise to rely to any extent on lotteries for their support. During the past few years the hospitals have lost much of the support they used to get from the charitable public. The sums obtained from lotteries appear large in the eye of the public, and may have a further adverse influence on subscriptions.

A Ministry of Health in Ireland.

There are signs of a renewed agitation in certain quarters in favour of the establishment of a Ministry of Health in Ireland. Last week the Irish Nurses' and Midwives' Union held a public conference on health matters in the Mansion House, Dublin. After a long discussion, in which several nurses and medical men took part, the following resolution was carried unanimously: "This meeting calls upon the Government to appoint a Ministry of Health and Public Welfare, so that the very urgent needs of the community in regard to health services may be considered and dealt with without delay."

VIENNA.

(From our own Correspondent.)

Birth-rate and National Development.

In a recent study, based on the figures of the birth-rates of the leading European countries, Dr. Hecke has directed special attention to conditions in the Austrian Republic. He gives the following data: As in the rest of Europe, the birth-rate in Austria was increasing up to the year 1902, when it stood at 216,717, but the increase was not proportionate with the increase of population. From 1902 the birth-rate fell constantly; in 1913 it reached 189,536, although the population was still increasing, owing to diminished death-rate. During the war the drop was catastrophic, going below 50 per cent. of the 1913 figure, but it has gradually risen again since 1919, being 148,721 in 1922—that is to say, 23 per 1000 inhabitants, against 32 in 1902. In the war years about 300,000 children less were born in Austria than might normally have been expected—a loss far outweighing that of the killed (180,000 men). Thus the age composition of the population has been materially altered. The proportion of children below 10 years is very much smaller; males aged 20 to 40 years, 326 per 1000 before the war, now number 306 per 1000. The boys below 10 years are now 164, against 202 per 1000 before the war. The drop in numbers of females, whilst not so marked, is easily discernible. In large towns and industrial districts the condition is more evident than in rural provinces or small towns. The constant increase in the ratio of adults is one of the chief reasons of the housing shortage. A comparison with statistics obtained for the year 1840 by Roscher, tells us that at that time out of 1000 inhabitants there were below 15 years of age: in Prussia 370, in Belgium 323, and in all other countries a figure between these two figures. But for 1920, in Austria, the figure was 270, showing that an increase of housing accommodation had become necessary in the next few years. All eugenists agree that the diminishing birth-rate is largely due to deliberate birth-control. Taking legitimate births in Vienna, we find that, in 1884, of 1000 married females of fertile age (15 to 45), there were born 214 living children; there were 186 in 1902, 112 in 1912, and 98 in 1921. The corresponding figures for illegitimate births per 1000 unmarried women of 15 to 45 are 84, 54, 32, 15. It must not be forgotten that the percentage of females of the child-bearing age is still increasing, owing to the increasing birth-rate of 40 to 20 years ago. Thus illegitimate births are much more controlled than legitimate births. Dr. Hecke believes that scarcity of food is the chief motive of suppression of births. For the regeneration of a race it is important to improve not only the morals of the population, but also to improve the economic situation of parents. Severe taxation of bachelors or spinsters, preference of parents in all public and private appointments, and facilities of all kinds for persons having two or more children, are only a few of the possible incentives in this connexion. The situation is improving. In parts of the country where economic conditions have taken a decided turn for the better the birth-rate is sufficient, and the number of marriages is constantly increasing. In 1903 47,000 marriages were registered, against 77,000 in 1921. Encouragement of emigration is eliminating a surplus of active persons, so that the remainder can more easily obtain food and housing in their native country, and thus found families.

Pasteur and Jenner: Celebrations in Vienna.

The centenary of Pasteur's birth was duly celebrated by the University of Vienna in a series of lectures as well as by a number of papers published in medical periodicals. The Pasteur Institute in this city also published in honour of Pasteur a synopsis of its work, and students of the University were invited to hear a series of special papers dealing with Pasteur's work. Perhaps even more appreciation, however, was accorded to the centenary of the death of Edward Jenner, whose discovery of vaccination was rapidly put to a severe test in Vienna. It is perhaps not widely known that the family of the Austrian Ambassador in Constantinople was one of the first on the Continent to be vaccinated, an occurrence which introduced vaccination into Austria. The Imperial family, which had suffered from small-pox, was soon won over to the new method, and their example served as an inducement to the whole Empire. It may safely be said that Jenner's vaccination—or rather, "equination," for the first lymph used in Vienna was from horse-pox, not cow-pox—began its triumphal spread through Middle Europe from Vienna. A solemn ceremony was held in the University, and the various learned societies and corporations also celebrated the day. In this country, where vaccination is practically compulsory, the once dreaded disease is almost extinct; an occasional outbreak of disease imported from the Balkans only serves to emphasise the customary immunity.

The Cemeteries of Vienna.

Some 60 years ago the municipality of Vienna obtained a large tract of ground on the outskirts of the city for a central cemetery. The original area has had to be increased six times, and now occupies 2½ million square metres (about a square mile). Over a million bodies lie there—i.e., about 40 per cent. of all persons who have died in Vienna since 1869. There are 32 other cemeteries at the disposal of the municipal authorities, covering a total area of about another square mile, and containing about 1½ millions of graves. Some of these smaller burial grounds are already completely occupied, and will have to be closed down entirely. As the daily mortality amounts to about 100 persons, this means that over 30,000 corpses have to be disposed of per year. There is in Vienna nothing to prohibit the interment of the body of a Jew or of a Mahomedan amongst those of men of other faiths; the cemetery is a municipal institution, subject to no religious restrictions. The task of disposal of so many corpses is greatly eased, however, by the opening of the new crematorium, which will shortly deal with about 20 per cent. of the total material.

Vienna, Feb. 6th.

BRITISH INDUSTRIES FAIR.

THE British Industries Fair, the ninth in unbroken succession, was opened at the White City on Feb. 19th and closed to-day (March 2nd). Of the nine sections into which the fair was divided, covering almost every department of daily life, two were devoted to drugs, chemicals, and scientific instruments, and the display in these sections was one that did credit to British manufacturers, a feature of the fair being that all exhibitors were the actual manufacturers of the goods shown. A good idea of the amount of material exhibited in all the sections taken together may be gained from the fact that there were some four miles of stand frontages.

Drugs and Chemicals.

The display by Boots Pure Drug Company, Ltd., Nottingham, showed a large range of fine chemicals. Anæsthetics, analgesics, antipyretics, and hypnotics were prominent features of this stall, while attention may be directed to chloramine-"T," para-toluene-sodium-sulpho-chloromide, containing chlorine which is readily liberated on contact with protoplasm, and acriflavine, diamino-methyl-acridinium chloride, both of which possess powerful antiseptic and germicidal properties. Another feature of the exhibit was the organic arsenical drug "Stabilarsan," which is a compound of salvarsan and glucose, and for which is claimed a lower toxicity than other arsenobenzol preparations, while it is sufficiently stable to be supplied ready for use in solution. Messrs. A. Boake, Roberts and Co., Ltd., Stratford, London, E., in addition to chemicals, essential oils, perfumery materials, and flavouring essences in great variety, made a feature of sulphume, a gaseous product of burning sulphur, from which all impurities are removed by washing in water. It can be used as a germicide, insecticide, and "raticide." The British Drug Houses, Ltd., Graham-street, London, N., showed a pure glucose for use in surgical and medical practice; a preparation of barium sulphate guaranteed free from the dangerous soluble salts; contramine, whose employment in the treatment of syphilis is familiar; and duogen, a stable solution of hydrogen peroxide. The British Dyestuffs Corporation, Ltd., Spring Gardens, Manchester, offered for inspection many fine chemicals for research work, and a large selection of microscopic stains. Acriflavine and euflavine (a neutral acriflavine), benzidine, a blood reagent, dimethyl-para-amino benzaldehyde, for detecting the presence of abnormal quantities of urobilinogen in urine, and sulphanilic acid used in Ehrlich's diazo reaction in testing urine. The exhibit of Messrs. Burroughs, Wellcome and Co., Snow Hill Buildings, London, E.C., gave special prominence to the "Wellcome" bismuth salts and sodium salicylate in non-caking flakes, together with a large number of alkaloids and alkaloidal salts. Another noteworthy medicinal preparation shown was "Moogrol," a promising therapeutic agent for use in combating leprosy. A display demonstrated the successive stages in the production of "Kharsivan" and "Neokharsivan," an all-British preparation of proved utility, to replace salvarsan and neosalvarsan. Details of the preparation of "Tabloid" gland products and of "Iodicin," an organic combination admirably adapted for the intensive administration of iodine, were also shown, and there were displays of sera, vaccines, and tuberculins, of microscopic stains, of medicine cases, and a variety of "Tabloid" and "Soloid" products.

Messrs. W. J. Bush and Co., Ltd., Ash Grove, Hackney, London, E., manufacturers of flavourings, soluble and fruit essences, showed a wide range of essential oils answering to the characters and tests of the British Pharmacopœia, 1914, and to the British Pharmaceutical Codex, 1911; and Messrs. Arthur H. Cox and Co., Brighton, drew particular attention to their British formamint and aspirin tablets. A very attractive display of toilet preparations was a feature of this firm's exhibit. Messrs. May and Baker, Ltd., Battersea, London, S.W., exhibited a large number of bismuth salts, iodine preparations, mercurials, and anti-syphilitics. These latter included arsenobillon (606), novarsenobillon (914), arseno-argenticum, eparseno (132), a stabilised solution of amino-arseno-phenol, and luatol, a neutral solution of sodium and potassium bismuthyltartrate, for intramuscular injection. Sanagen Co., Ltd., Kennington Park-road, London, were also amongst the exhibitors, and excellent collections of disinfectants were shown by Messrs. Burt, Boulton and Haywood, Ltd., Salisbury House, London Wall, E.C.; by the Gas Light and Coke Company, Dauntsey House, Frederick's-place, London, E.C.; and by the United Alkali Makers and Chemical Manufacturers, Cunard Building, Liverpool.

Miscellaneous.

The McKay Artificial Limb Co., Ltd., Blackfriars-road London, S.E., demonstrated the remarkable results which can be obtained by their mechanical limbs; the Berkefeld Pump Filter Company, Sardinia House, Kingsway, London, W.C., showed a new form of their filter for hospital use, the feature being a supply of filtered water at any temperature; the Fulham Pottery and Cheavin Filter Company, Fulham, London, S.W., were also represented, many forms of domestic and portable filters being shown.

Attention may be called to the many products of Messrs. Chivers' and Sons, Ltd., of Histon, Cambridge, jellies, jams, marmalade, and coffee essence, as well as non-alcoholic beverages. The excellence of some of the processes of preservation adopted by this firm has already been referred to in these columns. An adaptation of sponge rubber to the purposes of chair seats and bicycle saddles was shown by the Sorbo Rubber Sponge Products, Ltd., Sorbo Works, Woking, Surrey. The seats made of this substance possess a remarkable resiliency, and further extensions for the use of rubber in this connexion suggest themselves. Whether such seats would unduly retain heat is a matter for trial. Lastly, reference may be made to Messrs. Harbutt's (Bathampton, Bath, and Ludgate Hill, London, E.C.) plasticine exhibit. This substance, while primarily intended for educational and recreational purposes in schools, has found many uses in the physical laboratory and in the practice of medicine and surgery. In the latter category it has been used for ear plugs, protecting broken skin, making splints, and for demonstration work in the medical school.

Where such a large number of exhibitors are concerned it is possible in a brief article to mention a few only of the exhibits having special reference to medicine, surgery, and hygiene.

SUSSEX PROVIDENT SCHEME.—The Sussex Provident Scheme for Hospital and Specialised Medical Services, which was launched by Dr. J. F. Gordon Dill at the end of 1920, has just closed its second year's working. It has now a membership of 4000, almost entirely drawn from Brighton and Hove where the scheme originated. The receipts for 1922 were £1984 13*s.* 4*d.*, but it should be explained that the great bulk of the members were not forthcoming until the last three months of the year. The administration expenses were £159 5*s.* 10*d.* The medical institutions of Brighton were paid altogether £1010 17*s.*, the share of the Royal Sussex County Hospital being £628 10*s.* 4*d.* Other medical payments amounted to £55 7*s.* Local workmen and their employers contributed £1501 4*s.* The year 1923 commenced with a balance of £99 16*s.* The executive committee state that they welcome the coöperation of hospitals in the county; the sum received by each hospital depends entirely upon the number of members treated in their wards.

Correspondence.

"Audi alteram partem."

DELAYED AND IMMEDIATE ANAPHYLACTIC SHOCK.

To the Editor of The Lancet.

Sir,—The first of the two cases recorded by Dr. J. Fawcett and Dr. J. A. Ryle in the issue of The Lancet for Feb. 17th is of especial interest because of the fact that the patient had received the sensitising dose of serum 19 years before she received the dose which called forth the anaphylactic symptoms. So far as I am aware this is the longest recorded interval between the two doses, though I have not searched the literature of the subject lately to find out whether a longer has been noted. Seven years has been the longest period I have myself met with; but I have been furnished with the notes of an unpublished case in which the period was 12 years.

The case is also of peculiar interest, as the writers point out, because the symptoms and especially those due to heart failure, though delayed, were extremely severe. Such cases, however, are not unknown. In an address published in your columns some five years ago (The Lancet, 1918, i., 323), it was pointed out that the anaphylactic state might be shown by unusual severity of the symptoms irrespective of the length of the latent period, though usually the more severe cases are associated with a short latent period; and I have before me now the notes of a patient, a soldier, who, having been wounded on July 31st, 1917, was injected with antitetanus serum the same day and subsequently had six or seven more injections, the last on Feb. 4th, 1918. At 3.30 p.m. on April 10th, 1918, he received another injection of 500 units of antitetanus serum. On April 16th, between 7 and 8 a.m.—i.e., about 5½ days later, he suddenly became ill with vomiting, dyspnœa, cyanosis, collapse, and a universal eruption of urticaria. The rash lasted all day and it was two days before the patient recovered from the attack. The usual circulatory symptoms in these cases are increased frequency (up to 160 per minute), irregularity, and enfeeblement of the pulse. The latter may not be felt at the wrist, though it is rare for this want of radial pulse to last for so long a period as in the case recorded by Dr. Fawcett and Dr. Ryle.

I am inclined to the opinion that more of these cases occurred amongst soldiers during the war than is usually believed. During the 2½ years I was in charge of the Grove Military Hospital, Tooting (January, 1917, to July, 1919), I met with eight cases of anaphylaxis, four of which were severe; and I might have missed seeing some of these cases had it not been known to the staff of the hospital that I took an especial interest in the subject. I agree with Dr. Fawcett and Dr. Ryle that the prognosis is usually favourable and that the patients are not in so serious a condition as they seem to be. Still, I have had an anxious time with several patients during the last 25 or 26 years, though I have been fortunate in not having met with a fatal case.

The writers are of the opinion that ordinary serum sickness is an anaphylactic response. I am not persuaded that such is the case. I understand that nothing resembling ordinary human serum sickness has been observed in experiments on animals. Possibly, however, normal serum sickness may be taken as evidence that the subject of it has been supersensitised. The clinical evidence is scanty, but such as it is, it goes to show that if a person undergoes an attack of ordinary serum sickness after a primary injection of serum, he is more likely to have an anaphylactic attack after a second injection than is the person who did not suffer from serum sickness after the first injection.—I am, Sir, yours faithfully,

E. W. Goodall.

North-Western Hospital, Hampstead, Feb. 19th, 1923.

AURAL DISCHARGE IN CHILDREN.

To the Editor of The Lancet.

Sir,—The article in The Lancet of Feb. 17th on the Treatment of Aural Discharge in Children by Mr. Harold Barwell will excite much interest. It may be pointed out that there is an additional or alternative treatment suitable for many cases of chronic otorrhœa—namely, zinc ionisation. It is over 20 years since Prof. Leduc published his articles on the treatment of local sepsis by zinc ionisation. To determine which cases of chronic otorrhœa are suitable for the application of this method of treatment we have to decide on the cause of chronicity. 1. Is this due in any particular case to the irritation of septic fluid in the ear? 2. Is it possible to fill the whole of the cavity containing the septic fluid with zinc solution, or is a portion of the cavity inaccessible without operation? 3. Is there any factor in addition to sepsis responsible for the continuance of the suppuration, such as polypi, or granulations, or cholesteatoma? 4. Are areas—the naso-pharynx, nose, and mouth—which communicate with the ear in a septic and inflamed condition? This would make reinfection of the ear almost inevitable and a continuance or a recurrence of the discharge almost unavoidable. Zinc ionisation is an antiseptic method of treatment, and if we are to form our judgment by the results obtained in cases theoretically suitable we are bound to admit that it is efficacious.

I should estimate that the percentage of cases of chronic otorrhœa in children due to simple tympanic sepsis is approximately 50 per cent. These cases can be cured in two or three visits. In a further 25 per cent. the otorrhœa is kept up by sepsis with polypi or granulations, or with muco-purulent rhinitis, or inflamed tonsils. In these cases it is desirable to convert the dual or triple condition of sepsis + polypi, or sepsis + rhinitis, &c., into the single condition, sepsis, before attempting to sterilise the middle ear by ionisation. These cases will require on an average six to eight visits. The remaining 25 per cent. are those in which there is sepsis in a position where it is not possible to introduce the zinc solution without some form of operation. These include most of the mastoid and attic cases.

With regard to the question of enlarged tonsils and adenoids favouring the continuance of otorrhœa, the writer has observed at the ionisation clinics many patients in whom the tonsils and adenoids have been removed without cessation of the otorrhœa, and in whom ionisation readily produced a cure. Frequently other cases are cured by ionisation alone, although there is moderate enlargement of the tonsils. A small number of cases of otorrhœa with muco-purulent rhinitis or inflamed tonsils are seen, and in these ionisation of the ear without treatment of the nose or throat seldom effects a cure. I do not believe from experience that moderate enlargement of the tonsils, or a moderate degree of adenoids apart from inflammation, prevents the cure of otorrhœa by ionisation, or has any considerable influence in causing a recurrence of the discharge.

I am, Sir, yours faithfully,

Devonshire-place, W., Feb. 22nd, 1923. A. R. Friel.

VACCINE TREATMENT IN PERNICIOUS ANÆMIA.

To the Editor of The Lancet.

Sir,—The recent paper on pernicious anæmia by Drs. Panton, Maitland Jones, and Riddoch in which they "take the strongest possible exception" to the recommendation of Dr. Hurst and others to use an autogenous vaccine in the treatment of the disease, and Dr. Hurst's reply in your issue of Feb. 24th, furnish a striking study in contrasts as to the outlook taken by different observers in regard to the directions and methods by which further carefully directed clinical research may appropriately be directed. My experience leads me, without hesitation, to agree with Dr. Hurst's contention that a pathological bacterial condition in the duodenum may be an important ætiological factor in the disease in question, and that the condition may be favourably influenced by appropriate vaccine treatment, always provided that all collateral indications are attended to. I would go even further and suggest, on the strength of numerous bacteriological investigations of the flora, as ascertained from material obtained at the operating table, that a faulty bacterial condition in the *small* intestine plays a more important rôle in the ætiology of many common diseases than is at present known.

Our knowledge of the normal conditions under different dietetic régimes is at present too limited to admit of any conclusions, but Dr. Hurst's observations on the presence of streptococci in the cases of pernicious anæmia recorded are useful and stimulating. If one were to venture a word of criticism on his conclusions, it would have been useful to have a more complete statement of the results of the bacteriological examinations, more particularly as to the presence or absence of coliform organisms, and if present, Dr. Hurst's reasons for disregarding them. In making this comment, I fully appreciate the force of the importance he attaches to the hæmolytic nature of the streptococci found. Dr. Hurst's observations are valuable in focusing attention on a subject of great clinical importance that is at present almost entirely neglected. The explanation of this neglect is, it appears to me, to be largely found in the study of the contrasts in outlook referred to above, and this in turn is mainly due to the present unfortunate division between the outlook and work of the skilled laboratory worker and the clinician.

Increasing importance is now being given to the study of the pathology of the living as opposed to study in the dead-house. There is equal need for the fuller recognition of the importance of the study of the bacteriology of the living; results of real practical value, however, are not likely to be quickly obtained without a more sane and wise coöperation between the work of the skilled laboratory worker and the clinician than at present obtains.

I am, Sir, yours faithfully,

Edinburgh, Feb. 24th, 1923. Chalmers Watson.

ORAL SEPSIS IN RELATION TO PERNICIOUS ANÆMIA.

To the Editor of The Lancet.

Sir,—The contribution in The Lancet of Feb. 10th to the subject of pernicious anæmia reopens the question of the relation of oral sepsis to the disease. Drs. Panton, Maitland-Jones, and Riddoch there state: "We are not of the opinion that oral sepsis has any proven ætiological significance in pernicious anæmia, although we freely admit that it cannot but be detrimental to a patient's health, and may at times produce secondary anæmia such as is caused by any other chronic suppurative process." This conclusion had its origin in the observation of 104 cases of pernicious anæmia under treatment at the London Hospital, in which the question of oral sepsis was particularly inquired into. Out of this number pyorrhœa was present in 47; 13 patients had false teeth; 10 carious teeth; in 12 the teeth were noted as clean; in 9 cases as good. In 21 of the whole series the mouth was described as free from sepsis.

With respect to this report, it seems to me, as a laryngologist, that two points of criticism may be raised. First, that the teeth are not the only source of mouth infection, and, secondly, that a bacteriological examination of the saliva could alone determine whether the mouth was, or was not, free from sepsis. The teeth may be sound and the gums healthy, and yet marked sepsis may be present. What is generally overlooked is that the tonsils are frequently the focus of chronic sepsis, especially when of the "flat" variety, suggestive that they are healthy. Their septic state, however, is revealed by pressing them; it is then that pus is squeezed out of the crypts and appears on the surface. This condition of the tonsils is often overlooked. I may mention a case in point. During the war an officer on active service in France came under notice for throat trouble. He complained of constant coughing and a persistent irritation of the fauces, compelling frequent swallowing of the saliva. His tonsils being "flat" they were reported as being healthy. Nevertheless, since the trouble continued, despite treatment, he was at last invalided home. When he came to me I at once suspected tonsillar infection. I pressed one of his tonsils and pus oozed out of the crypts. After the necessary treatment he was soon able to return to duty. A "flat" tonsil, although in an infective state, may be unaccompanied by signs indicative of its condition. This emphasises the necessary precaution in all cases of examining the tonsils in order to exclude them as a source of sepsis before asserting that sepsis is not present in the mouth. Again, in addition to the tonsils, it has to be remembered that nasal suppuration is also a frequent cause of infected mouths. Personally I have never seen a case of oral sepsis without septic tonsils or nasal suppuration being present. In my opinion these are the two chief causal factors in oral sepsis, and each of these is commonly overlooked.

Mouth disinfection, then, becomes an important matter apart from the teeth and gums, and tonsillar infections, unsuspected and untreated, may, after all, have a determining influence in the onset of pernicious anæmia. A recent paper[1] by Kopeloff of New York shows that bacteriological research, based upon fractional gastric analyses, establishes that the bacterial flora of the stomach is the resultant of purely external factors—namely, food and saliva. His investigations have determined that the stomach is not itself the focus of septic organisms, but that the latter are derived from the mouth. This again adds weight to the necessity of mouth disinfection and the exercise of care not to overlook chronic suppuration of the tonsils. I am, Sir, yours faithfully,

William Lloyd.

Brook-street, Grosvenor-square, W., Feb. 23rd, 1923.

AUTO-INTOXICATION OR DEMENTIA PRÆCOX?

To the Editor of The Lancet.

Sir,—The letter you published last week by Dr. Burr Ferguson leads me to make the following observations confirmatory of his remarks.

The symptom perhaps the most distressing to the sufferer from chronic intestinal auto-intoxication has its origin in the action of the toxins in the blood upon the cerebro-spinal system, and the relief afforded by freeing the subject from this condition is expressed at once in the alteration of the mental outlook of the individual. These patients experience a feeling of misery and mental depression, a want of control over their temper, a want of capacity to form decisions even on trivial subjects, an inability to concentrate on any mental occupation, a dull heavy pain in the head, sleeplessness, or, on the other hand, a constant desire to sleep which affords no sense of refreshment, but leaves the sufferer in a dull and stupid condition. These people are not only a source of misery to themselves, but they tend to wreck the happiness of those who have the misfortune to be associated with them. Very frequently neuralgia, especially of branches of the fifth nerve, is complained of. In some cases it becomes so severe as to be epileptiform in type. Epilepsy in varying degrees of severity is by no means a very infrequent complication. I believe that paralysis agitans, dementia præcox, disseminated sclerosis, and many cases of mania owe their origin to the fouling of the blood-supply of the brain by intestinal toxins or to secondary infections produced by them.

This condition renders the individual very liable to break down under the influence of any continued or severe mental strain, as is not infrequently seen in our daily life, when it is regarded as the result of overwork. During the war I saw a large number of cases of shell shock. In all the patients suffering from this condition whom I was able to observe, I found that stasis existed in a marked degree. The normal subject does not manifest this reaction to shock. This view is held also by Dr. McNair Wilson, who tells me that he was able to confirm it by many experiments in healthy and in toxic individuals. Besides this state of mental atrophy the muscular system suffers in a similar measure, partly because of the imperfect nutrition, but largely, perhaps, on account of the changes in the cells in the brain that control them.

---

[1] American Journal of the Medical Sciences, vol. clxv., No. 1, 1923.

The schoolboy is often regarded as stupid, dull, and inattentive, when his disability is brought about solely by the presence of toxins in his circulation. A marvellous change may occasionally be effected in his mentality and general usefulness by the removal of a controlling appendix and the consequent purification of the contents of his intestinal canal. Certainly our soul is in our abdomen.

I am, Sir, yours faithfully,
Feb. 26th, 1923. W. ARBUTHNOT LANE.

L'AFFAIRE SPAHLINGER.

To the Editor of THE LANCET.

SIR,—Last October Mr. Spahlinger generously sent me a supply of his serum through the mediation of Dr. Arthur Lynch. The patient was apparently hopelessly ill with acute pulmonary tuberculosis; every symptom of the disease was markedly present, and I expected her illness would very soon have a fatal termination. Since April, 1922, I had been in attendance and prescribing vaccines and other so-called remedies for tuberculosis, with only a rapid downhill progress as a result. After a few injections of Spahlinger's serum considerable improvement took place—all the symptoms of the disease ameliorated, and the physical signs improved to a considerable degree. I can only describe the improvement as miraculous.

After more than 25 years in medical practice I can fairly claim to have had some experience. The patient is now doing well, and I am confident will in a few more months be quite convalescent, and I am quite sure all the improvement is solely due to the serum introduced by Mr. Spahlinger, of Geneva, as I have resorted to no other medication. The patient's relatives are so impressed with her recovery that they have given £600 to the appeal fund, and I have contributed my mite myself.

Your suggestion that Mr. Spahlinger should permit his serum to be tested for results by a committee of medical men is only doing again what was done in 1913–14, when about 35 cases went through the treatment at the City of London Hospital, St. George's Hospital, and the French Hospital in London.

I am, Sir, yours faithfully,
JOHN D. RICE.
Carbis Bay, Cornwall, Feb. 22nd, 1923.

To the Editor of THE LANCET.

SIR,—Permit me to add my testimony to the value of Henri Sphalinger's work on tuberculosis to that of Dr. Wansbrough Jones as set forth in his admirable letter appearing in your last issue.

I have known all about this work since Spahlinger first came to this country in 1913. I have been to Geneva, not several times, but many, in order to follow up that work, and as a consequence I have nothing but praise for the man, whom I am proud to call my friend, his ethical attitude towards the medical profession, his scientific methods, his singleness of purpose, and the clinical results of his serum and vaccines. I have often been urged to crave space in your columns for the publication of some of these results, but I have steadfastly refrained from so doing because I saw at least two objections to such a course. The one was that the time was not ripe. It had already been proved in the case of Spahlinger's "communication" to the Académie de Médecine, and strongly emphasised in the case of his "communication" to the Académie des Sciences, that it is a grave mistake in tactics to extol a remedy until you can deliver the goods. Having signed both these documents I knew, and could have called the weary weight of my letter-bag to witness. Premature proclamation offers too good an opportunity for the heathen to rage furiously together, and for the people to imagine a vain thing. Another consideration which restrained me was that the cured cases for which I could personally vouch were too few to be conclusive; for however convincing clinical results may seem to one observer to be, they are not, and ought not to be, convincing to the scientific world at large. They require multiplication and confirmation. So I held my hand, waiting and hoping for the day when Spahlinger would be able to place his complete sera and vaccines at the disposal of those qualified to subject them to experiment and control. Alas! I am still waiting. Spahlinger's work has been held up for want of funds, and he has very properly declined to submit his remedies to critical investigation until those remedies can assume their final and complete form. Such remedies as he has been able to produce since the armistice are not complete; they are, indeed, very partial, and even so, they are forthcoming in quantities relatively minute.

The closing paragraph in your leading article (Feb. 17th) suggests that Mr. Spahlinger should "submit to the independent investigation of his remedy." The answer is that there is nothing which Mr. Spahlinger so ardently desires. Since 1918 he has been praying fervently for the day when he might be in a position, by following this course, triumphantly to vindicate his scientific bona fides. But he cannot. The remedy does not exist. What little did, for a brief moment, exist, is long since exhausted. And the trouble is that it never can exist, until and unless he is relieved of his financial embarrassments. A large number of British physicians and bacteriologists, many of them at my own instance, have from time to time journeyed to Geneva to examine into the possible value of Spahlinger's treatment, and I understand that each one has returned deeply impressed with the fact that the Spahlinger methods represent an entirely new departure which is pregnant with hopeful possibilites. There is, on the showing of the Red Cross attitude alone, no doubt whatever that a strong prima facie case has been established. Nor, unfortunately, is there any doubt that, under present conditions, it is out of the question to pursue that case to a logical, demonstrable conclusion.

In these circumstances, what possible objection can there be to a press campaign to obtain the necessary funds? Why should not the enlightened members of the charitable public be informed, as they presumably would wish to be, that a possible and highly probable solution of the riddle of the White Scourge is standing in rags at their doors, in imminent danger of death by starvation? For the information of the heathen above-mentioned, I feel constrained to add that Henri Spahlinger has never accepted one centime in the way of remuneration or out-of-pocket expenses from anyone, during the whole of the ten financially anxious years that he has been engaged upon this work.

I am, Sir, yours faithfully,
LEONARD WILLIAMS.
Harley-street, W., Feb. 24th, 1923.

To the Editor of THE LANCET.

SIR,—I am in agreement with you in speaking of the lack of funds to produce the Spahlinger remedies as a tragedy. After what I have seen of the results of the treatment I am convinced that it would be a tragedy of the first magnitude for humanity if the world is to be deprived of the benefits of Mr. Spahlinger's discoveries.

I have used the serum in various forms of tuberculosis in Switzerland and have been profoundly impressed with the results obtained. I have also visited Mr. Spahlinger's Institute in Geneva and examined a large number of patients who have received treatment by his serum and are now enjoying complete freedom from symptoms and leading normal lives several years after receiving treatment. From the history of these cases it is a fair inference to make that all would now have been dead without Spahlinger's serum. In addition, I have seen and examined many patients in London treated in 1913–14 who undoubtedly owe their lives to the success of this treatment.

Numerous medical men and experts from all parts of the world have visited Geneva, inspected the Institute—where, I may say parenthetically, that every assistance is given to visiting medical men and every facility granted in both clinical and bacteriological respects—and to the best of my knowledge no adverse report has been issued. As a result of my own observations I have come to the conclusion that it is no exaggerated claim to make that in Mr. Spahlinger's serum and vaccine we have a remedy which far surpasses in efficiency anything previously known to the medical world.

I cordially endorse all that is said in Dr. Wansbrough Jones's letter in your issue of Feb. 24th, and fervently hope that funds will be forthcoming to enable Mr. Spahlinger to produce his remedies in such quantity that they will soon be available for the whole world.

I am, Sir, yours faithfully,

JAS. A. W. WATTS.

Late Physician to the Palace Sanatorium, Montana.

Woburn-place, London, W.C., Feb. 25th, 1923.

ERGOTISM WITH GANGRENE OF THE TOES.

To the Editor of THE LANCET.

SIR,—In THE LANCET of Feb. 17th, p. 336, there is a note on a case of supposed ergotism with gangrene of the toes, reported by Mr. R. E. Kelly and Dr. W. J. Dilling at the Liverpool Medical Institution on Feb. 1st. Surely to prove that the patient's two attacks were really due to ergotism needs further evidence than was adduced. It is true that ergot was present in the rye bread eaten by the patient, who was a Polish Jew, aged 42 years; but the age of the patient, the fact of the patient being a male and a Polish Jew, the fact that there was no hæmorrhage on removing the toe, the absence of general arteriosclerosis, the recurrence of attacks, and the non-extension of the gangrene, are all equally points in favour of the diagnosis of thrombo-angiitis obliterans (non-syphilitic arteritis obliterans of Hebrews). It is not stated whether the tendency to gangrene was symmetrical; in thrombo-angiitis obliterans usually one foot only is affected at first. Gangrenous ergotism is hardly known to occur at present in England or even in Central Europe, whereas quite a number of cases of thrombo-angiitis obliterans have been and are observed amongst the Polish Jews of London.

I am, Sir, yours faithfully,

London, Feb. 18th, 1923. F. PARKES WEBER.

JENNER CENTENARY AT WARSAW.

To the Editor of THE LANCET.

SIR,—I have pleasure in informing you that the Warsaw Society of Hygiene celebrated at a meeting held on Jan. 23rd the anniversary of the death of the great Jenner, and in giving the following brief details of the history of vaccination in Poland. The first public vaccination establishment in Poland was established at Vilna in 1808. A decree of the Grand Duke of Warsaw (Frederick Augustus I., King of Saxony), published in 1811, made compulsory the vaccination of all children in the first year of life. In 1823 a Government vaccine establishment was opened in Warsaw; Poland had then been partitioned and Warsaw was the capital of the Polish "Congress Kingdom," within the Russian Empire, its king being the Czar Nicholas I. This establishment, after 100 years of existence, has now been closed, the present Polish Government having established a new institute. The establishment now closed had during the whole period only four directors: the chief medical officer of the province of Warsaw, Dr. Masrynski (1823–1843); Dr. Le Brun, chief physician of the Infant Jesus Hospital, and his assistant, Dr. Mühlhausen (1843–1887), and the writer of this letter (1887–1922). Latterly the institute has been under municipal administration, the Russian Government having refused to continue the subvention; since 1903 it has been housed in a building designed by myself and erected by the municipal authorities of Warsaw. This building will now be used as the municipal chemical and bacteriological laboratory. After the abolition of autonomous Polish sanitary administration in 1870, sanitary affairs, including vaccination, were neglected by the Russian Government, and small-pox epidemics were frequent. For many years I endeavoured, without result, to have vaccination made obligatory in Poland with penalties for default. Finally I suggested to the Warsaw City Council that general vaccination might be enforced in the city by application of the above-mentioned decree of 1811; this was done, with the result that small-pox epidemics disappeared. During the recent German occupation the total vaccination of the population of Poland was undertaken with lymph produced in our establishment. After the war vaccination was not, at first, enforced, but in 1920 a law was passed making obligatory the vaccination of all children under one year of age and the revaccination of all persons of Polish nationality in the country. In a paper on Jenner which I read at the above-mentioned meeting, I wrote as follows: "If we were to make the bills payable between nations, not monetary, but cultural and economic, the international balance-sheet would show interesting results —results which unfortunately are, and perhaps will for long be neglected by the politicians. But it is certain that the principal place, as regards hygiene, belongs to England. England was the original home of sewerage systems and other methods of sanitation, and for many advances in medicine—for example, those connected with antisepsis and anæsthetics—the world stands deeply in her debt."

I am, Sir, yours faithfully,

Warsaw, Feb. 14th, 1923. JOSEPH POLAK.

INFECTIVE ENDOCARDITIS IN THE ELDERLY.

To the Editor of THE LANCET.

SIR,—"If there is a primary cardiac rheumatism," Dr. F. J. Poynton says (THE LANCET, Feb. 3rd, p. 218), "why should it not conform to other great infections and be of all grades of severity?" The occurrence of infective endocarditis in later life, I think, is apt to be overlooked, amongst the infirmities of age, and the slowing of all processes, whether of health or disease.

A woman of over 70 showed an indolent ulcer of recent appearance, on the right shin. Soon after, another, she thought, was about to come, on the left shin. I saw there a small purpuric patch and began to reason that the cause of ulceration was not an initial abrasion, but a necrotic area in the vascular periphery. Closer observation revealed a number of minute ecchymoses. A new view could now be taken of other symptoms, assumed at first to be of a chronic or degenerative order. These were an irregular cardiac rhythm, slight systolic murmur at apex and aorta, albuminuria, and mild pyrexia. The first ulcer healed, the second formed, and has remained chronic; albuminuria was transient; the heart varies; the patient, never confined to bed, moves about.

A man of 75 came under observation two years ago. He had taken to bed with pulmonary congestion and pyrexia; had muscular tremors, small pupils, and lapsed into somnolence from which he was readily roused; an aortic diastolic murmur was audible. Tremor, an erratic temper, and a soporific habit he has retained. Recently he was taken with dyspnœa, accentuation of aortic murmur, œdema of feet, and a minute hæmorrhagic rash upon the legs.

In cases like these histories are hard to elicit; septic foci may not be found, blood examination, if made, may prove indecisive, autopsies are not likely to follow for verification. But digitalis and perchloride of iron will have their place in treatment, and the course of that senescence will have interest to one who has rightly recognised in it a progressive cardiac infection.—I am, Sir, yours faithfully,

Bristol, Feb. 21st, 1923. DAVID A. ALEXANDER.

THE DISPENSING OF PRESCRIPTIONS.

To the Editor of THE LANCET.

SIR,—My attention has been drawn to the letter in your issue of last week signed by Dr. Clark Trotter, the medical officer of health for Islington, on the dispensing of prescriptions. I have no knowledge of the campaign in Islington to which Dr. Trotter refers, but I have no doubt the facts, if they are available to my Society, will be investigated by them, for they certainly call for some investigation.

My object in writing at this stage is to express my great regret that a professional man holding the important post of medical officer of health should have thought fit to take a method of dealing with the matter which, to say the least, is not what the authorities or the public expect from a public servant in Dr. Trotter's position. If there was anything seriously wrong no one knows better than Dr. Trotter that the Ministry of Health should have first of all been communicated with and, either through them or directly, the attention of my Society called to any ground of general complaint.

I deprecate the reference in the letter to the remuneration which Dr. Trotter assumes the pharmacist receives for dispensing. It is not the argument one expects from professional men. I express no opinion as to the adequacy or otherwise of that remuneration, as it has no bearing on the alleged delinquencies; whether the remuneration is satisfactory or not, the exercise of due skill and care on the part of the pharmacist is essential, and I am satisfied it will be found that pharmacists in the main do their duty.

I think the medical profession will share my regret that Dr. Trotter has been so unwise as to excuse his letter by inferring that because so many charges have been made against the panel doctor it was wise to "show up" the chemist. The medical profession well know that pharmacists have never brought any charges against panel doctors, and his comment is obviously open to the retort that if the charges against panel doctors are well founded it is no answer to them, if it be a fact, that other people are open to similar charges.

It is difficult to understand why the letter was written, but more difficult to appreciate the action of a medical officer of health attempting to create and to foster antagonism between the medical and pharmaceutical professions. Fortunately, although Dr. Trotter may have succeeded in depreciating the pharmacist in the eyes of the public, the great mass of his colleagues in the medical profession from personal experience know that such general charges as he has brought against pharmacists are in no way founded.—I am, Sir, yours faithfully,

E. T. NEATHERCOAT,
President, Pharmaceutical Society of Great Britain.

Bloomsbury-square, London, W.C., Feb. 27th, 1923.

THE OPPOSITION TO PANEL PRACTICE.

To the Editor of THE LANCET.

SIR,—I have read Dr. S. G. Askey's letter in THE LANCET of to-day's date together with your remarks. It would be interesting to know what meaning you wished to convey by the words: "There exist a certain number of non-panel doctors who, being hostile to the Act, persuade patients that they get better treatment by attendance as private patients." My difficulty is to persuade patients not to waste my time with their complaints against the Act. Can you name one non-panel doctor who persuades patients as you state or does "a certain number" in your unhappy choice of words mean "none"?

I think we are entitled in a scientific journal to expect your words to convey their obvious meaning. It is not as if you were some politician making reckless statements, and when called to account trying to get out of it by saying you meant something else. Dr. Askey is not alone in imputing to you a hostile attitude towards non-panel doctors.

I am, Sir, yours faithfully,
GEORGE F. GRANT, M.B., C.M.

Brixton-road, S.W., Feb. 24th, 1923.

*** We wish that the insured person, as such, could select the practitioner by whom he wishes to be treated, but that is far from the hostility to non-panel doctors attributed to us. The insured person, who also pays private medical fees, must be persuaded in his mind that he is getting something thus that he would not get otherwise.—ED. L.

The Services.

ARMY MEDICAL SERVICES: NEW DIRECTOR-GENERAL.

Maj.-Gen. Sir William B. Leishman, K.C.M.G., C.B., has been appointed Director-General, in succession to Lt.-Gen. Sir John Goodwin, K.C.B., C.M.G., D.S.O., with effect from July 29th next.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. S. H. Woods is placed on Ret. List with the rank of Surg. Capt.

Temp. Surg. Lieut. (D) D. Barker is transferred to the permanent list.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. F. P. Lauder retires on ret. pay.

Maj. A. H. Jacob and Capt. A. S. Plant retire receiving a gratuity.

The undermentioned to be Lts. (on prob.): Capt. W. L. S. Cox (late The Queen's R.), Lt. H. A. Gilkes (T.A. Res. of Off.), and Second Lt. F. C. H. Sergeant (late R.F.A., Spec. Res.).

ARMY RESERVE OF OFFICERS.

Capt. T. D. Inch resigns his commn.

Army Dental Corps.

Capt. C. D. Currie, late Spec. List, to be Capt.

TERRITORIAL ARMY.

The undermentioned officers relinquish their commns. and retain their rank except where otherwise stated: Lt.-Col. A. Ogston (with permission to wear the prescribed uniform), Maj. A. L. Heiser, Capts. G. H. Hunt (Bt. Maj.), G. G. Middleton (granted the rank of Maj.), W. Burt, W. Scarisbrick (granted the rank of Maj.), W. L. Hibbert, T. P. Kilner, T. H. Somervell, G. W. M. Andrew, C. S. J. Kearney, J. L. Moir, R. R. Lishman, F. P. Gibson, A. C. Smith, C. A. Raison (granted the rank of Maj.), V. M. Wallis, P. J. Smyth, W. H. Milligan, J. B. Hogarth, E. G. T. Poynder (granted the rank of Maj.), F. P. Smith, J. W. Rammell, F. Standish, O. K. Wright (granted the rank of Maj.), T. G. Buchanan (granted the rank of Maj.), F. H. Davies, H. W. Greig, F. G. Harper, W. E. H. Bull, W. Tresawna, F. Simmers, J. Browne (granted the rank of Maj.), N. T. K. Jordan, J. H. Cumming, C. D. Relton, W. S. Soden, and G. D. Newton.

Capt. A. Don, having attained the age limit, is retired, and is granted the rank of Maj.

General Hospitals: The undermentioned relinquish their commns. and retain their rank except where otherwise stated: Lt.-Cols. J.. Marnoch (Bt. Col.), A. W. Mackintosh (with permission to wear the prescribed uniform), and R. Waterhouse; Maj. T. V. Crosby; Capts. N. I. Spriggs, J. S. C. Douglas, F. Alcock, and J. Clark.

Capt. W. J. Stuart, having attained the age limit, is retired, and is granted the rank of Maj.

Capt. A. F. Hewat to be Maj. (Prov.).

2nd Eastern General Hospital: Capt. H. H. E. Scatliff resigns his commn. and is granted the rank of Maj., with permission to wear the prescribed uniform.

Sanitary Companies: Capt. (Bt. Maj.) W. J. F. Mayne and Capts. J. M. McQueen, D. Porter, and A. White relinquish their commns. and retain their rank.

Supernumerary for Service with the O.T.C.: Capt. R. J. McN. Love (late R.A.M.C.) to be Capt. for service with the University of London O.T.C.

TERRITORIAL ARMY RESERVE.

Capts. A. J. Campbell, A. M. Deane, W. N. West-Watson. and A. G. Williams relinquish their commns. and retain their rank.

Maj. T. R. Kenworthy, from Genl. List, and Capt. A. A. McWhan (from 1st London Sanitary Co.) to be Majors.

Obituary.

PROF. CHR. SAUGMAN.

Christian Saugman's sudden death at the age of 59 has robbed Denmark of a great personality and a prominent landmark in the campaign against tuberculosis. Saugman was born in 1864, and soon after he had completed his medical training he developed pulmonary tuberculosis. He underwent sanatorium treatment at Dr. Brehmer's Institute in Görbersdorf, and though the disease even at this stage was severe and advanced, it was arrested, and he returned to Denmark to take up general practice. In 1895 he read a paper before the Danish Medical Society in which he outlined his scheme for establishing the first sanatorium in Denmark. His appeal for funds met a prompt response, and by 1899 Vejlefjord Sanatorium stood ready equipped with Saugman as its chief medical officer. Since then this sanatorium has been the model on which many other Scandinavian sanatoriums have been established, not so much in the actual building and organisation as in the spirit of its management. He remained at his post till death, which did not come unexpectedly. A chronic brochiectasis and recurrent attacks of bronchitis had impaired a constitution enfeebled by pulmonary tuberculosis and by a virile spirit which had demanded far more of his body than it was capable of giving. An attack of gall-stones, from which he had long suffered, came on while on a trip to Munich to see Sauerbruch operate. He underwent operation in hospital at Copenhagen and died of heart failure on Feb. 7th.

CHRISTIAN SAUGMAN.

Outwardly Saugman was not cast in a grand mould, but no one who had the privilege of meeting him could avoid coming under his spell. He had what the Danes call "gnist," the Germans "geist," a quality for which we lack a word. Like many men who make their mark in the world, he had no great sense of humour, what humour he possessed did not obtrude itself. Courteous and candid, he more than once found these two qualities in conflict; his courtesy was always candid, and, whenever it was possible, his candour was courteous. But there were occasions when Saugman called a spade a spade, and on a recent occasion, when the statistics of Vejlefjord Sanatorium were juggled with by a Danish colleague to prove that a liberal dietary was harmful for the tuberculous, Saugman's reply, published in the *Journal* of the Danish Medical Association, was candid and nothing more.

In the treatment of tuberculosis, Saugman was to Scandinavia what Trudeau was to the United States. One of his first achievements was to show by a statistical comparison, of the results obtained at Vejlefjord and in Switzerland, that the disease is as amenable to treatment at sea-level as in an Alpine climate. This discovery brought sanatorium treatment to the door of the poorest patient. When Saugman began work at Vejlefjord he was no mean laryngologist, and he had a well-equipped throat department. But he gradually became convinced that tuberculosis of the larynx must be cured by curing the lungs, and that local treatment is apt to be harmful. Forlanini's work on artificial pneumothorax found a keen advocate in Saugman, who, by introducing the manometer, made this operation comparatively safe. It was in the year 1906 that Prof. Saugman induced his first artificial pneumothorax, except for two done previously by Murphy's method without a manometer and giving large doses of gas at infrequent intervals. About two and a half years later Dr. Holmboe visited him, learnt his technique, returned to Norway, and a little later inaugurated a highly successful pneumothorax on a dying Englishman, who was responsible for the introduction of this means of treatment to England in 1910, and who lives and works to this day. Saugman induced artificial pneumothorax on over 600 patients, involving many thousands of actual injections. On the occasions of the ninety-eighth and the one hundred and fifty-sixth case sudden death occurred, but after that he experienced no accident.

The success of artificial pneumothorax and the disappointments experienced with cases in which pleural adhesions prevented collapse of the lung led Saugman to seek other means of splinting the lung and he found them in the thoracoplastic operations, to the technique of which he contributed much. As a student he had had a taste for surgery, and after he had passed middle age he turned himself into a surgeon, performing his own thoracoplasties. With a great capacity for conscientious detail, quick of eye and nimble of finger, Saugman became a brilliant operator.

One more achievement must be mentioned. Saugman proved that the third stage case—the case hitherto commonly regarded as being qualified for sympathy without optimism—can often be restored to comparative health and usefulness. His remarkable success in this class was the result of his teaching each patient how to order his life in every detail hour by hour and day by day as long as the disease was smouldering. In his report for 1920 he showed that every fourth patient discharged from the sanatorium in the third stage could expect to be still fit for work ten years later. Saugman was to have given a lecture on lung collapse at the Royal Society of Medicine in May, and his friends in England had arranged to celebrate the occasion.

Dr. S. Vere Pearson writes: "Prof. Saugman was one of the world's most thorough of medical healers. His first-rate ability as sanatorium doctor was founded upon personal experience as an invalid, upon very wide study of his subject, upon his thoroughness, and upon the kindliness of his disposition. In his quickness and dexterity as an operator, in his grasp of the essentials of asepsis, in his mastery of the methods of diminishing shock and pain, he showed himself to be amongst the foremost of the surgeons of Europe. It was these qualities, combined with the ever-anxious, skilled, and personally intimate after-care of the patients who had undergone operations at his hands, that contributed to results more successful than those obtained by others. His patients, too, both before and after operation, were not in urban nursing homes, but in a beautifully situated, well-conducted sanatorium, and in the hands of this excellent physician. Such a combination of skilled operator with able physician is rare.

Throughout his life Saugman was a keen scientific worker. Though so busy and versatile—his sanatorium accommodated 112 beds—he kept full and systematic notes about his patients. He was a methodical and rapid worker, a good organiser and manager, a wide reader of medicine, and an able linguist. As chairman of one of the sections at the London International Conference of Medicine in London, with comparative ease he spoke many of his remarks alternately in four languages. The medical library at Vejlefjord was most representative and up to date. He took a keen interest in the various forms of light treatment, and his patients, among whom were cases of non-pulmonary tuberculosis, had the benefit of the latest forms of artificial sunlight. He was a master radiologist, especially with chests, and expert at ordinary physical examination. His scheme for classifying his patients[1] was devised because other systems appeared to him to lack value when put into use. He rejected the Turban-Gerhardt classification, since the vast majority (' over 90 per cent.' he said) of his cases were too advanced to come into any class other than Class III. His writings were frequent, always interesting, and well done."

Prof. Saugman was beloved by all with whom he came in contact, but above all by his patients, always his first consideration. Some of his scanty leisure was devoted to pursuing his interest in missionary work, and in the summer of 1921 he made a tour of the mission stations in Greenland. He leaves a widow, one daughter, and two sons. He is buried on the premises of the sanatorium whose guiding genius he was for so many years.

CONSTANCE LONG, M.D. BRUX., L.S.A.

Dr. Constance Long, who died recently in New York of pneumonia following influenza, spent her childhood as one of a large family in the neighbourhood of Reading. In her early youth she was very delicate, but she triumphed over physical weakness, and pursued her studies energetically. After leaving school she qualified as an art class teacher in what was then known as the School of Science and Art, South Kensington. She took up the study of medicine at the London (R.F.H.) School of Medicine for Women when she was about 23, with the idea of going abroad as a medical missionary, but eventually was not strong enough for foreign service. After qualifying L.S.A. and obtaining the M.D. Brux. in 1896, she held the posts of resident medical officer to the Clapham and Battersea Maternity Home, and resident medical officer at Dr. Barnardo's Home, Hawkhurst, Kent. During her tenure of office there was an outbreak of diphtheria in the village; there were 40 cases in the Orphanage, but thanks to Dr. Long's prompt use of antitoxin, then first becoming generally known, she did not lose a single case. Later she established herself in general practice at Crouch End and built up a successful career. She held the post of surgical clinical assistant at the New Hospital for Women and other clinical assistantships at the Royal Free Hospital and the Evelina Hospital. For many years she gave courses of lectures in first-aid, home nursing, and the care of children for the L.C.C. and other educational bodies, and then specialised in psycho-therapeutics.

Dr. Constance Long held the office of President of the Association of Registered Medical Women for two years in succession. She was one of the two women doctors elected on the Advisory Committee (Insurance Act) which discussed the Government proposals for Health Insurance in 1911, and in the autumn of 1919 she was one of the three medical women invited by the Women's Board of the War Work Council of America to attend the International Medical Women's Conference in the United States. Immediately upon her return from the States she was seized with serious illness, which necessitated operation. Upon her recovery she continued to practise as a consultant, applying principles acquired during a study of psycho-analysis with Dr. Jung of Zürich. She was a woman of wide interests; it was her sympathy with the psycho-neurotic patient met with in general practice that first urged her to the study of the new methods of treating this type of patient. She was, moreover, a hard and steady worker, and the translation of Jung's papers on Analytical Psychology under her editorship was an admirable piece of work. Her propaganda work for analytical methods included the delivery of lectures to various bodies. Some of these lectures were published during 1920 in a volume " The Psychology of Phantasy."

Dr. Long's death removes a medical woman whose breadth of outlook and wide knowledge had made her well-known and respected by her professional colleagues. Dr. Jung regarded her as an honoured collaborator. Dr. Long took little part in polemics, but when she spoke at psychological gatherings she was sure of a large and attentive audience.

WILLIAM PRIOR PURVIS, M.D., M.S., B.SC. LOND., F.R.C.S. ENG.

Mr. Purvis, who died on Feb. 13th, was a well-known practitioner in Southampton. He had exceptional qualifications. He became B.Sc. Lond. in 1889 and then began to study medicine at St. Thomas's Hospital. He qualified M.B. with honours in three subjects in 1892, and B.S. in 1893. In 1894 he proceeded to the M.D., and in 1896 M.S. in the University of London. In 1894 he became F.R.C.S. Eng. He held important residential posts at St. Thomas's, and later went to Southampton as house surgeon at the Royal South Hants and Southampton Hospital. For two years he served in the South African War as a member of the Southampton Volunteer Ambulance Corps.

On return from South Africa, Mr. Purvis took up private practice, and was elected to the staff of the Royal South Hants and Southampton Hospital, where he was senior surgeon and surgeon in charge of the ear, nose, and throat department at the time of his death. He was also attached to the Shirley Children's Hospital. Mr. Purvis had a high reputation as a surgeon, and was always ready to help and advise his colleagues. His generosity to his poorer patients was well known. He was a Past Master of Freemasonry and a keen member of the Hampshire County Cricket Club and other organisations. His loss will be felt throughout the county.

HEATON CLARK HOWARD, M.R.C.S. ENG.

Dr. Heaton Clark Howard, who died on Feb. 12th, at the age of 67, after a brief illness from blood poisoning, was the youngest son of the late Rev. Thomas Howard, Headmaster of the Grammar School, Newchurch, Rossendale, Lancashire. Dr. Howard received his medical education at St. George's Hospital (where he died), and qualified in 1880; he then settled in Clapham, where he practised throughout his professional life. An occasional contributor to the medical press, Dr. Howard attracted considerable attention in 1914 by an article[1] in which he described the results of his use of a liniment, prepared from raw potato-juice, in the treatment of gout and other painful conditions. Dr. Howard took an active part in local affairs. Among his appointments were those of chairman of the Works Committee of the School for the Indigent Blind, and surgeon-major to the St. John Ambulance Corps. He was an athlete of considerable prowess; in 1877 he won the United Hospitals Athletic Club silver cup (three miles championship).

THE LATE DR. RUTH M. SLADE.—Dr. Ruth Mary Slade, who died at Belfast on Jan. 15th as the result of an attack of broncho-pneumonia, was the daughter of Major S. Craig and the widow of the late Rev. E. H. Herbert Slade, formerly Government chaplain in the Punjab. She studied medicine in the University of Belfast and graduated in 1919; she took up practice in that city, and held the posts of assistant in the Belfast Hospital for Sick Children, the Samaritan Hospital, and the Maternity Hospital, and was also medical officer of the Salvation Army Home at Thornedale. Her kindly disposition and professional ability gained her the respect and regard of her medical colleagues and a wide circle of patients.

Medical News.

University of Oxford.—The Vice-Chancellor has approved the following appointments of demonstrators for one year from Michaelmas term, 1922. Department of Human Anatomy: Dr. M. H. MacKeith, Dr. W. W. Wagstaffe, Miss Beatrice Blackwood. Department of Physiology: Mr. H. M. Carleton, Dr. C. G. Douglas, F.R.S., Dr. E. G. T. Liddell (for three years). Department of Biochemistry: Dr. P. C. Raiment and Mr. G. L. Peskett.

In a Congregation held on Feb. 17th the degree of Doctor of Medicine was conferred on William Siegfried Dawson, Trinity College; Frederick Greig Hobson, New College; and William Tregonwell Collier, Balliol College.

University of London.—At a meeting held on Feb. 21st the Senate appointed Mr. H. J. Waring to be their representative at the celebration of the 800th anniversary of St. Bartholomew's Hospital in June, 1923, and Mr. Waring and Prof. H. R. Kenwood to be their representatives at the Thirty-fourth Congress of the Royal Sanitary Institute to be held at Hull in July–August, 1923.

The Graham Legacy Committee have reappointed Dr. V. R. Khanolkar to the Graham Scholarship in Pathology for two years from April 1st next. On this occasion the value of the scholarship is £300 a year. The reappointment was made on the recommendation of the School Committee of University College Hospital Medical School, at which Dr. Khanolkar's researches have been carried on during the past three years.

University of Paris.—During the spring a "cours de perfectionnement" in dermatology and venereal diseases will be held at the Clinique de Dermatologie et de Syphiligraphie, Hôpital Saint-Louis, under the direction of Prof. Jeanselme. The dermatological course will begin on April 9th, the venereal diseases course on May 23rd; the fee for each course is 150 francs. Lectures will be held in the hospital museum and in the amphitheatre of the clinic (Salle Henri IV.), 40, Rue Bichet (10e), Paris. The courses will include clinical, laboratory, and X ray demonstrations. A certificate will be issued at the conclusion of the course to those who have attended. A detailed programme will be sent on application to Dr. Burnier, Chef de Clinique à la Faculté, Pavillon Bazin, Hôpital Saint-Louis.

At the Clinique Médicale, Hotel-Dieu, an Easter "cours de revision" on Recent Ideas on Clinical Practice and Application of Laboratory Methods to Diagnosis will be held under the direction of Prof. A. Gilbert and Dr. M. Villaret, beginning on March 24th and comprising 34 lectures. Visits will be made to the Paris hospitals each morning, and there will be clinical and microscopical demonstrations. A certificate will be issued at the conclusion of the course, for which the fee is 150 francs. Foreign medical men are admitted. Applications and payment for both these courses must be made to the Secrétariat de la Faculté (Guichet No. 3), Faculté de Médecine, Rue de l'Ecole de Médecine, Paris.

London Hospital Medical College.—A lecture on Advances in the Treatment of Skin Disease by Light will be given by Dr. J. H. Sequeira on Thursday, March 8th, at 5 P.M., in the anatomical theatre of the College. The lecture will be open to senior students of the hospital and to post-graduates.

Central Council for District Nursing in London.—The eighth annual report of this Council was presented at the annual meeting held on Feb. 22nd. It was announced that since in all the counties adjoining London, with the exception of Middlesex, county nursing associations have undertaken the provision of district nurses, it has been decided to concentrate upon those areas which fall within the County of Middlesex. Preliminary steps have been taken in the districts of Acton, Hanwell, Wood Green, and Ealing, and an association has been established at Friern Barnet to which a starting grant of £20 has been given. The scheme, drawn up by the Queen Victoria Jubilee Institute in conjunction with certain of the larger approved societies, for the nursing of insured persons at a payment per visit has been in operation in most parts of London. The amount of maternity nursing carried on by the district nursing associations continues to increase. It has been ascertained that the average number of nurses employed by all the federated associations is 568. Uncovered areas have been discovered in certain districts in South-East London—e.g., Dulwich, Herne Hill, Gipsy Hill—and there are also unnursed streets in parts of Eltham and in Streatham and Mitcham. It is hoped that if financial help is forthcoming neighbouring associations may be induced to provide for these areas.

A stained-glass window is to be placed in St. Mary Magdalene's Church, Lincoln, to the memory of Dr. Edward Mansel-Sympson, physician, antiquary, and archæologist. Dr. Mansel-Sympson was a devoted churchman.

Royal Dental Hospital of London.—The annual general meeting of the governors will be held at the hospital, Leicester-square, W.C. 2, on Thursday, March 15th, at 5 P.M. All governors are invited to attend.

North-East London Post-Graduate College.—The spring intensive course at the Prince of Wales's General Hospital will begin on March 12th and will last for 14 days. It will include lectures and demonstrations of clinical methods and cases, and work in the general wards and special departments of the hospital.

Children's Clinic, Western General Dispensary.—An additional lecture in connexion with the course on Children's Diseases at this clinic (Cosway-street, London, N.W. 1) will be given by Sir William Bayliss on March 5th at 5 P.M. The subject of the lecture will be the Use of Saline Injections in the Treatment of Disease. Members of the profession are invited to attend.

Rontgen Society.—A dinner to celebrate the twenty-fifth anniversary of the foundation of the Rontgen Society will be held on Thursday, March 15th, at the Hotel Cecil, Strand, London, W.C. The price of the dinner, including wine, will be 17*s.* 6*d.* per head. Each member is permitted to bring one guest. Members are asked to notify the hon. treasurer at the Society's house, 33, Newton-street, London, W.C. 2, not later than March 4th, how many tickets they will require.

Brompton Hospital for Consumption and Diseases of the Chest.—A special course in tuberculosis will be held at this hospital from March 19th to 24th. Among those taking part are Dr. G. E. Beaumont, Dr. W. C. Bosanquet, Dr. L. S. T. Burrell, Dr. M. Davidson, Mr. Tudor Edwards, Dr. A. H. Gosse, Sir James Dundas-Grant, Sir Percival Hartley, Dr. A. C. Inman, Dr. S. Melville, Dr. A. L. Punch, Mr. J. E. H. Roberts, Dr. Batty Shaw, Dr. C. Wall, Dr. R. C. Wingfield, and Dr. R. A. Young. The course will include demonstrations in the wards, laboratories, and special departments, and lectures on the treatment of symptoms, sanatorium treatment, and prognosis in pulmonary tuberculosis.

University of Edinburgh: War Memorial.—On Feb. 19th Lord Balfour, as Chancellor of the University, unveiled memorial tablets on which the names of nearly 1000 victims of the war are inscribed. It is still open to Edinburgh graduates who have not yet subscribed for this object to share in the commemoration. Subscriptions to complete the cost are required, and will be welcomed. It is desired that the cost should be met by many gifts of small sums, so that the scattered sons and daughters of the University may feel that they have a part in this mark of honour to those of their colleagues who gave their lives. Subscriptions should be sent to Principal Sir J. Alfred Ewing at the University.

Ladies Medical Golfing Society.—The spring meeting will be held at West Hill Golf Club, Brookwood, on April 6th. In the morning a medal round under handicap will be played. The Canny Ryall Challenge Cup will be awarded for the best net return and the Captain (Lady Briscoe) is presenting a memento. A scratch prize will be presented by Lady Goadby, a senior handicap prize by the Society, and a junior handicap prize by Mrs. Hetherington. The afternoon will be devoted to Foursomes v. Bogey. Entries should be sent to the hon. secretary, Mrs. Laming Evans, 50, Seymour-street, London, W. 1, before March 29th.

Aberdeen Royal Asylum: Annual Report.—Dr. R. Dods Brown, the physician-superintendent, states that in 10·7 per cent. of the admissions to the asylum during the year mental worry or anxiety was ascribed by the friends of the patients as being the cause of illness. A few cases were resultant on the death or illness of relatives, but in the large majority the cause of worry was financial loss. In 68 cases bodily ill-health was considered to be an important factor in the causation; 42 patients were suffering from senility. Dr. Brown lays stress on the value of voluntary treatment as being early treatment. In many cases before a patient can be certified as of unsound mind the disease is well advanced. Voluntary treatment can, unfortunately, still only be given to such as are in a financial position to become private patients. During the year 196 patients were admitted, 79 males and 117 females, being 13 fewer than in 1921; 65 were discharged recovered, 44 relieved, 49 not improved, 87 died, and there remain on the register 769. The income was £63,776 and expenditure £55,920, the surplus being carried to the general revenue account.

Messrs. J. and A. Churchill announce the forthcoming publication of a new edition (the fourth) of "Diseases of the Eye," by Sir John Parsons, F.R.S., and of "Practical Midwifery," by Dr. Gibbon FitzGibbon, Master of the Rotunda Hospital, Dublin.

HÔPITAL MARITIME, BERCK-PLAGE.—From March 26th–31st an Easter course of six lectures on the Treatment of Osteo-articular and Ganglionic Tuberculosis will be given by Dr. E. Sorrel. The course will include demonstrations of operations, drainage, preparation of plaster appliances, &c. Those wishing for information should apply to Dr. Parin, Hôpital Maritime, Berck-Plage, Pas de Calais, France.

EXTENSION OF EAST LANCASHIRE INFIRMARY.—On Feb. 22nd, at the annual meeting of the East Lancashire Royal Infirmary at Blackburn, a scheme for enlarging the hospital was announced, involving an outlay of £200,000. £70,000 for this purpose will be available for the town's memorial fund. Last year the collections from the workpeople reached nearly £11,000.

SMALL-POX IN THE MIDLANDS.—Six fresh cases have been notified at Doncaster and four cases at Bentley, a neighbouring township. At Clowne, Derbyshire, after a visit from one of the medical officers of the Ministry of Health, it has been decided to prosecute persons failing to notify small-pox cases and persons suffering from the disease who expose themselves in public.

THE LATE ALFRED EDWIN HARRIS.—The death of Dr. A. E. Harris, for nearly 30 years medical officer of health of Islington, has removed one of the pioneers of public health work. After qualifying L.R.C.P. & S. Edin. in 1876 he became resident medical officer to the Ophthalmic and Aural Hospital at Cork. He then practised in Gosport for five years before being appointed whole-time medical officer of health to the County Borough and Port of Sunderland. In 1882 he became medical officer of health and administrative tuberculosis officer of Islington. One of his earliest publications was on the Preventable Causes of Infantile Mortality, wherein the appointment of health visitors was foreshadowed, and many developments of the child welfare movement prophesied. Dr. Harris was a man of vision, and his forcible personality enabled him to do valuable propaganda work. His interest in the prevention and prompt treatment of infectious diseases led to special efforts directed to their reduction in Islington, with noteworthy results. Dr. Harris retired in 1921 on reaching the age of 70, but the results of his work will endure as part of the foundation on which much of the modern public health work throughout the country has been built.

ROYAL SUSSEX COUNTY HOSPITAL.—In the annual report of this hospital for 1922, submitted to the court of governors on Feb. 21st, it was stated that financial straits necessitated the closing down of more than half the hospital beds on and after Oct. 1st. When the position of the hospital was realised many persons came forward to help. In combination with the economies effected by the closing of beds, an anticipated deficit of £10,000 was turned into a credit balance of £5359 2*s.* 3*d.* at the close of the year. This happy result, the report went on to say, was mainly due to Mr. Harry Preston, and to Colonel Sir Charles A. Woolley, who added another £1000 to the £5000 which he had given earlier in the year. During the past few years Mr. Preston had been the instrument of raising nearly £15,000, including a personal expenditure of some £3000. Mr. R. Ball Dodson, chairman of the board of management, announced the receipt of a letter from the Voluntary Hospitals Commission approving of a grant of £3950 to the Royal Sussex County Hospital on condition that the hospital undertook to reopen 50 of the closed beds on March 1st this year, and the remainder not later than Sept. 1st, the beds to remain open until the end of 1924. Mr. Ball Dodson said that the board had promised to open 50 beds on March 31st, which promise had been accepted; the others would be opened on Sept. 1st, and the board of management were thus able to accept the grant. Difficulties in the way of special pay beds had hitherto proved insuperable, but thanks to the action of the trustees of the late Sir John Howard there was every prospect of 20 beds for this purpose being opened in the near future. These beds were intended to meet the needs of those who were unable to bear the expenses of a serious operation and treatment in a private nursing home. Another interesting item in the report referred to the enormous development in the orthopædic work in the X ray, electro-therapeutic, and massage departments. "Even if the present demands are to be met, great increase of accommodation is essential." The governors gave sanction for the erection of a one-storey extension to the east of the main building, and the adaptation of the adjoining basement, for the accommodation of these departments, in accordance with plans already approved, and under the conditions necessary to secure the British Red Cross grant for the purpose. The grant was one of £2000, and was given in 1919, but delay had been wise, as accommodation, which it had been expected would cost £15,000, would now be provided for a sum of between £4000 and £5000. The report alluded to the Sussex Provident Scheme, stating that the accounts of the hospital showed a substantial gain in income from that source; and the comparison of numbers of patients treated in 1921 and 1922 showed that 2530 in-patients had been admitted, compared with 2928, and 5084 out-patients, compared with 7054. In 1922, 211 beds were closed during the last quarter. The average cost per bed occupied for the whole year, £174 1*s.* 9*d.*, though £1 14*s.* less than in 1921, was greater than it would have been had all the beds been open throughout the year, for the overhead charges necessarily remained much the same. During the first nine months the cost per bed occupied was £166 10*s.* 1*d.* per annum, and during the last quarter it rose to £196 16*s.* 10*d.*, notwithstanding many economies.

The Duke of Abercorn, Governor of Northern Ireland, has appointed Prof. Thomas Sinclair to be hon. surgeon and Prof. J. A. Lindsay to be hon. physician to his household.

BRIGHTON, HOVE, AND PRESTON DISPENSARY.—At the annual meeting of the governors on Feb. 13th the opinion was expressed that the difficult financial position of the dispensary was due to a certain extent to the great efforts being made in the district to aid the funds of the Royal Sussex County Hospital, where 125 beds were closed on Oct. 1st, 1922. The dispensary covers ground largely untouched by the County Hospital; among other activities it provides for home visiting of sick people, and therefore support should be given to both institutions. The excess of expenditure over income was £845 against £808 in the previous year, largely owing to the expenditure on the Hove Hospital. This branch of the dispensary costs £3500 annually, but subscriptions from Hove only brought in £784. The figures for the Hove branch show that 291 in-patients were admitted during 1922, and in the out-patients' department 870 casualties were treated, and 192 major and 290 minor operations were performed. At the parent establishment and the Preston branch 3258 new out-patients were seen during the year, and 1936 new patients were visited in their own homes by the district medical officers, who paid 9596 visits. Mention was made of the great difficulty which was being experienced in securing an honorary medical staff for the parent establishment at Brighton and the Preston branch.

AMERICAN MEDICAL ASSOCIATION: ANNUAL MEETING.—The next annual session of the Association is announced to be held at San Francisco from June 25th to 29th, the President being Dr. Ray Lyman Wilbur of Stanford University, California. The usual division of the scientific part of the proceedings into 15 sections will take place, and meetings will be held of the five councils—namely, Judicial Council, Council on Health and Public Instruction, Council on Medical Education and Hospitals, Council on Scientific Assembly, and Council on Pharmacy and Chemistry. Communications should be addressed to the Secretary of the Association at 535, N. Dearborn-street Chicago.

THE LATE DR. THOMAS HIGGINS.—On the evening of Feb. 11th a party of armed men visited the house of Dr. Thomas Higgins, of Stradbally, in the Queen's County, and demanded admission. This was at first refused, but after some conversation the leader was admitted. A couple of minutes later he rushed from the room ordering his men to fire. Dr. Higgins was then shot dead. It is conjectured that the object of the band was merely to destroy Dr. Higgins's house and farmyard without inflicting any personal injury. While in conversation Dr. Higgins appears to have gained possession of his visitor's revolver, and the latter in alarm ordered his men to fire. The reason for the crime is, of course, unknown, but it is believed that Dr. Higgins owes his death to the fact that one of his sons, Mr. Kevin O'Higgins, is Minister for Home Affairs in the Free State Government. Dr. Higgins is the first medical man to lose his life in the struggles which have been going on in Ireland for the past four years. His death will cause widespread regret in the medical profession. Dr. Higgins qualified L.R.C.P.Irel. and L.M. in 1881, becoming F.R.C.S.Irel. in 1887. He held the post of clinical assistant in the Rotunda Hospital, Dublin, before settling in practice. In Stradbally he was much beloved, and as coroner for Queen's County his sound judgment and careful investigation of cases were greatly appreciated. He represented the Queen's County both in the Council of the Irish Medical Association and in the Irish Medical Committee. Dr. Higgins leaves a wife and large family, two of his sons being members of the medical profession.

ROYAL MEDICAL SOCIETY, EDINBURGH. — The annual dinner was held in the hall of the Royal College of Physicians, Edinburgh, on Feb. 20th. The company numbered about 100. The chair was occupied by Dr. T. McW. Millar, the senior President, and the guest of the evening was Sir Humphry Rolleston. Other guests included Lord Murray, Lord Alness, Vice-Admiral Sir John Green, Colonel S. F. Green, Principal Sir Alfred Ewing, Sir Robert Philip, the Very Rev. Dr. Wallace Williamson, Dr. George Mackay, Dr. Byrom Bramwell, and Dr. W. G. Dun. Sir Humphry Rolleston, replying to the toast of his health, proposed by the chairman, referred to the age of the Society, which is now approaching 200 years. The Society was interesting in that, as a students' society, it had received a Royal Charter. He dwelt on the many advantages to be gained in its Fellowship, and particularly on the advantage of debate. The toasts of Sister Professions and of the Edinburgh Medical School—to the latter of which Sir Alfred Ewing replied—were then proposed. An interesting feature of the evening was the election of Dr. Byrom Bramwell to the newly instituted office of Hon. President.

Public Health Services.

THE MEDICAL SERVICE SUBCOMMITTEE AS A DISCIPLINARY TRIBUNAL.

A GOOD deal was said at the recent Guildhall Conference on insurance practice in regard to the medical service subcommittees, set up under the Insurance Acts to deal with questions arising between the insured person entitled to treatment and the practitioner providing that treatment. Although those tribunals are not as effective as they might be, it is ridiculous to speak of them as a sham, as a few examples taken from the latest report of the Medical Service Subcommittee for the County of London will show.

1. For breach of medical certification rules furnished in respect of an insured person on three occasions during 1922 a practitioner was cautioned. The Ministry of Health, on being referred to, decided not to withhold the supplementary grant on this occasion, but would feel bound to take more serious view of any further breach by the practitioner of the terms of service.

2. In a case in which a practitioner refused a certificate of incapacity to an insured person because she did not engage him to attend her at her prospective confinement, the practitioner was censured for failure to comply with his terms of service, and a sum of £15 was withheld by the Ministry from the supplementary grant, to be recovered from the practitioner by deduction.

3. An insured person complained of a fee of £5 charged for cauterisation of the nose and tonsillectomy by the partner of the insurance practitioner attending her. The subcommittee held that these services did not fall within the category of those properly to be undertaken by a general practitioner of ordinary professional competence and skill, and decided that the insured person was not entitled to recover the sum.

4. In the case of a practitioner living away from his surgery and not attending there between 1 P.M. on Saturday and 10 A.M. on the following Monday, complaint was made by an insured person of inability to obtain treatment. The subcommittee admitted its powerlessness to prescribe the distance at which a surgeon may or should reside from his surgery, but regarding the arrangements in this case as unsatisfactory asked the Ministry of Health to require the practitioner to rearrange, to the satisfaction of the subcommittee, his days and hours of attendance for the treatment of insured persons.

5. A patient complained that the insurance practitioner had not advised her need of a course of treatment for anæmia, did not recommend her to go to a specialist for some condition of the ear, and did not prescribe any treatment for a slight curvature of the spine. During the inquiry the practitioner admitted advising malt and oil, but did not order it as he understood that insurance practitioners should restrict the use of this preparation to patients suffering from tuberculosis. The subcommittee took the opportunity of stating that no such restriction exists; practitioners are at liberty to prescribe cod-liver oil and malt should the condition of the patient be such as to require it, provided only that it is not prescribed as a food. The committee decided that the complaint to provide adequate treatment had not been substantiated.

Parliamentary Intelligence.

HOUSE OF COMMONS.

TUESDAY, FEB. 20TH.

War Pensions Administration.

Mr. ADAMSON moved the following amendment to the Address on behalf of the Labour Party:—

> "But regret that, in view of the widespread dissatisfaction that exists amongst ex-Service men and the dependents of those who died as the result of war service regarding the provisions of the Royal Warrant and the War Pensions Acts, the unsympathetic administraion of the Pensions Ministry, and the curtailment of the responsibilities of local committees, no reference is made to the institution of a thorough inquiry by a Select Committee to consider what action is necessary to secure the full discharge of the solemn obligations entered into with those who suffered injury or death in the service of the country during the Great War."

He said that the Ministry of Pensions were obsessed with the desire for economy, and he protested against the fact that the nine principal officers in the Ministry who were Service men were not on an equal footing with the 50 who were non-Service men, and asked for a different composition of and wider powers for the area appeal tribunals and the establishment of a national appeal tribunal for the hearing of appeals from the area tribunals.

Major COHEN, as a responsible official of the British Legion, deprecated the putting down of the amendment, which amounted to a vote of censure on the Government. He did not think that the suggested Select Committee was necessary or desirable. There was no doubt that the Ministry was unsympathetic, but he blamed the bureaucratic system.

Mr. SYDNEY WEBB said so far as he had seen it he commended the administration of the Ministry of Pensions, and he would be sorry if the amendment was taken as a vote of censure. He supported the amendment because he wanted to help the Ministry to find out where its regulations were not working well. He hoped that the Government would signify how this inquiry was to take place and how assistance could be given to a department which was struggling with a herculean task.

Major ENTWISTLE said he agreed with the theory that if a man was accepted as an A1 man, and he broke down during the course of his service, he ought to be held to be entitled to a pension, but that was not the state of the Warrant at present and had never been so. If the Warrant was altered it would result in an increased charge of very many millions to the Exchequer. Once they opened the door to pensions being granted for all disability, irrespective of its cause, they had no check at all upon the expenditure that would result. Complaints of lack of sympathy were greatly exaggerated, and the same was true of the Lord Chancellor's Appeal Tribunal. He had not heard any complaints that the tribunals acted unfairly.

Major TRYON, Minister of Pensions, replying to the debate, said that he had one new announcement to make. The Government proposed to introduce legislation during this session to enable a pensioner to have his life certificate signed only once in six months instead of three. During the next year he hoped they would be able to save, not on the pensions, but on the administration, nearly £1,000,000 as against last year. If they cut out the medical services the cost of administration was only 9*d.* in the £. Before this amendment was put on the paper he had already called a meeting of the Advisory Committee. He would put before them the problems that had been raised in the debate and see how they could more fully use the voluntary effort which was so invaluable to them as a Ministry in getting into that close personal touch with the pensioners. In all discussions on the Ministry of Pensions its medical and surgical responsibility was generally overlooked, and yet since the Armistice the Ministry had spent over £60,000,000 on medical treatment of the sick and wounded and in allowances for the men and their families while the treatment continued. A large proportion of the patients had been restored to health and had resumed their civil occupations. At the present time the Ministry was responsible for a daily average of 25,000 patients in hospital (of these 12,000 were in hospitals owned, managed, and staffed exclusively by the Ministry), a daily average of 80,000 patients attending as out-patients at hospitals or clinics (of whom the larger number were attending clinics owned, staffed, and controlled exclusively by the Ministry), and over 1,000,000 cases of treatment had been dealt with by the Ministry in the past three years. It was the aim of the Ministry's medical service to carry on the medical attention of cases as long as there was the smallest chance of materially improving the man's condition. He had had an analysis made recently of 1000 cases taken at random of the discharges from hospital during the last 12 months, and he found that of the general medical and surgical cases 118 out of 1224 were discharged as completely recovered. The treatment and handling of ex-Service men suffering from nerve or brain trouble was a matter that had been constantly under discussion between himself and representatives of ex-Service men. Both his predecessors and himself had realised the importance of this question. The Ministry had 14 neurological hospitals and a large number of neurological clinics. The results of treatment had been very remarkable. In one neurological hospital devoted to the most serious cases out of 134 treated during 1922 only 9 had eventually to be certified as insane; of the remainder 68 were discharged recovered and 12 were transferred to other institutions, including some for industrial training. Between 1500 and 1600 cases passed through the neurological hospitals in a quarter. Of these on an average 20 per cent. were discharged fully recovered. The Ministry intended to carry the matter further by dealing directly with some of the most hopeful and suitable cases of ex-Service men actually certified as insane. The Ministry were going to start as an experiment separate arrangements for the treatment of selected certified cases of a hopeful type. The Government felt, at any rate, that the experiment was well worth making. They would begin tentatively with one or two small establishments and were taking steps to start the experiment at an early date.

On a division the amendment was negatived by 307 votes to 176—Government majority, 131.

The Address in reply to the King's Speech was then agreed to.

WEDNESDAY, FEB. 21ST.

Treatment of Mental Deficients.

The House went into Committee of Supply, Mr. J. F. HOPE in the chair.

On a vote of £10 in respect of certain public buildings,

Sir J. BAIRD, First Commissioner of Works, said that this was a token vote necessary to enable the Office of Works to put in hand an extension of the Rampton Institute for the treatment of persons of defective mentality who were violent and dangerous. The present accommodation was for 220 male patients and 148 females. The scheme now contemplated included the erection of additional units to accommodate 90 females and 110 males, additional nursing accommodation, and cottages for married staff. The scheme would take three years to complete and the cost would be £105,000.

Mr. HARRIS said the scheme was likely to involve an expenditure of something like £700 per head for each person provided for in the institution. It would, in his view, be very unwise to develop still further these institutions when there was a great difference of opinion among experts as to whether it was advisable to go on building these large institutions.

Sir J. BAIRD said that the Board of Control, whose responsibility it was to look after these unfortunate people, had come to the conclusion that institutions such as that for which he was asking this token vote were the best adapted for these cases.

Dr. CHAPPLE said there was no demand for this building. Had the Office of Works exhausted the possibilities of using the derelict buildings which could be found all over the country? No one should be incarcerated in any of these institutions who could possibly be kept out or treated in any half-way house or hospital.

Sir S. RUSSELL-WELLS appealed to members not to oppose the Government in this most beneficent work, which would bring relief to thousands of poor hard-worked and hard-pressed people. The wealthy could take steps to relieve themselves of their mentally deficient, but not so the poor. The removal of such afflicted creatures to institutions was best for themselves, a relief to their relatives, and a protection to the community. He had no doubt that many of the crimes committed in this country, especially those of a sexual nature, were committed by the mentally deficient, who, instead of being treated as scoundrels, should be put into institutions.

The Vote was agreed to.

The Blind Persons Act.

Mr. RHYS DAVIES asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether he had received representations from any quarter requesting that the Government should insist on all competent local authorities giving effect to the provisions of the Blind Persons Act, 1920; that, in view of the fact that the bulk of the blind people working in institutions for the blind were comprised within the membership of the National League of the Blind, provision should be made for representation of that league on the Advisory Committee on the Welfare of the Blind, and that in the appointment of home teachers for the blind preference should be given to competent blind persons over those who were sighted; and, if so, would he make a statement on the subject.—Sir W. JOYNSON-HICKS replied: The answer to the first part of the question is in the affirmative. As regards the second part of the question, representation of the National League on the Advisory Committee cannot be considered until they comply with the provisions of Section 3 of the Blind Persons Act, 1920, as to registration. As regards the third part of the question, the criterion is ability to do the work, and subject to this blind persons are, in fact, being appointed.

Institutions for Insured Consumptives.

Mr. BRIANT asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, what was the total accommodation provided in institutions, other than those under the control of Poor-law authorities, for insured persons suffering from tuberculous disease.—Sir W. JOYNSON-HICKS replied: The institutions approved by my right hon. friend for the treatment of tuberculosis in England, apart from Poor-law institutions, contain 19,240 beds. Of these 3310 beds are in children's institutions, but the remaining 15,930 beds are available for insured persons, although since the termination of sanatorium benefit no beds are specially reserved for such persons.

Sickness and Underfeeding.

Mr. D. G. SOMERVILLE asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, if the latest statistics of cases under the Health Insurance Acts showed any direct increase of sickness attributable to lack of sufficient nourishment.—Sir W. JOYNSON-HICKS replied: The latest figures available as to the extent of sickness amongst persons insured under the National Health Insurance Acts indicate that the aggregate amount of sickness during the past year fell short of the expectation on which the Acts were based and also of the actual experience of any pre-war year. So many factors affect the total expenditure on sickness benefit that it is impossible to assign variations in that figure to particular causes, but there is no direct evidence of an increase of sickness owing to the cause referred to by the hon. Member.

The General Nursing Council.

Mr. ALBERT ALEXANDER asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, why labour organisations representing working nurses had no representation amongst the nine nominees to the General Nursing Council for England and Wales; and whether he would take steps to repair this omission.—Sir W. JOYNSON-HICKS replied: Sixteen members of the General Nursing Council are nurses elected by the nurses on the Register. My right hon. friend sees no necessity for the appointment of additional nurse members, nor is this contemplated by the provisions of the Schedule to the Nurses Registration Act, which prescribes the constitution of the Council.

Financial Help for the Hospitals.

Mr. GILBERT asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether the Hospitals Commission had now distributed the whole of the £500,000 entrusted to them; how much had been allocated to hospitals in London; how much to those outside London; whether it was proposed to make any further grant; what was the total amount contributed to the Combined Appeal for the hospitals of London; how much had been distributed; and how much remained to be distributed.—Sir W. JOYNSON-HICKS replied: The whole of the £500,000 has not yet been distributed. The Commission allocated £225,000 to hospitals in London, and the whole of that sum has now been disbursed. £275,000 was allocated to the hospitals outside London. Of this sum £181,318 has been paid to date, and the Commission intend shortly to consider the distribution of the balance after the claims in respect of the 1921 deficits have been met. The Commission have not yet made any recommendation as to the continuance of State assistance after the present grant is exhausted. Full information in regard to the work of the Commission is contained in the interim report which will be issued on Thursday next. The Ministry of Health have no responsibility for the Combined Appeal for the hospitals in London. But the following information has been obtained from the Organising Committee. It is not yet possible to state exactly the total sum contributed to the Combined Appeal. The sum actually paid into the Organising Committee amounts to £392,100, of which £260,000 has been distributed, but large additional sums are yet to be received from two schemes which are still open.

THURSDAY, FEB. 22ND.

Reopening of Pension Appeals.

Mr. TREVELYAN THOMSON asked the Minister of Pensions under what circumstances, if any, it was possible for disabled ex-Service men or their dependents to be heard with regard to a fresh application for pension or treatment allowance when they had once been turned down by the appeal tribunal.—Mr. NICHOL asked the Minister of Pensions if any cases of ex-Service men, on which a decision had been given by a pensions appeal tribunal, had been reopened for consideration; and, if so, how many cases had been dealt with in this manner, and on what grounds.—Major Tryon replied: By the provisions of Section 8 of the War Pensions Act, 1919, the decision of a pensions appeal tribunal is final, and I am advised that it is not possible for appellants whose appeals have been rejected by a tribunal to have their cases heard again; nor, in fact, have any cases been so reopened and re-heard. In a small number of wholly exceptional cases (not more than six or seven) the Treasury has made a special concession.

Pensions and Insurance Benefit.

Major McKenzie Wood asked the Minister of Pensions whether, in fixing the amount of pensions, his department took into account money received by the pensioner in respect of national health insurance benefit.—Major Tryon replied: The answer is in the negative as regards disablement pensions, to which the hon. and gallant Member no doubt refers.

Maternity and Child Welfare in Scotland.

Mr. Sullivan asked the Under Secretary to the Scottish Board of Health what was the sum paid in Scotland for child welfare and maternity relief or help for 1919–20, 1920–21, 1921–22, and 1922–23.—Captain Elliot replied: The amount of Government grant paid in relief of local authorities' expenditure under schemes of maternity service and child welfare in each local authority,financial year ending in May was as follows: 1919–20, £64,692; 1920–21, £90,532; 1921–22, £235,832. The gross expenditure of local authorities in each year would be almost exactly double the amount of grant. The figure for 1921–22 is an approximation. The very large increase of grant in that year is due in the main to the increased supplies of food and milk given by local authorities, the cost of which amounted to more than half of the total expenditure. The grant for 1922–23 cannot yet be stated, but it is not expected to exceed £111,000.

Ex-Service Men in Lunatic Asylums.

Mr. Owen Parker asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether he had received protests from boards of guardians against the burden cast upon the rates owing to the action of the Ministry of Pensions in transferring to pauper lunatic asylums ex-Service men whose condition was alleged not to be due to or worsened by their military service; and whether he proposed to make a special grant towards their maintenance.—Sir W. Joynson-Hicks replied: My right hon. friend has received protests from some boards of guardians, but he can see no grounds on which he could justify a grant from other sources towards expenditure of this kind, which the Minister of Pensions is unable to defray.

Cost of Lunatic Patients.

Mr. Edwards asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether his attention had been called to the fact that the cost of lunatic patients chargeable to boards of guardians and maintained at asylums had so increased as to make the sum of 4*s.* per head repaid to the various unions under the Local Government Act, 1888, totally inadequate, and threw a heavy burden on local rates; and would he consider bringing in a Bill to amend this Act so as to provide for repayment of at least one half of the actual cost to them of every lunatic maintained in a county asylum.—Sir W. Joynson-Hicks replied: The amount of this grant was based on the estimated difference between the cost of maintenance in workhouses and in asylums respectively and, while it is true that the cost of maintenance in an asylum has increased since the amount was fixed, it is equally true that the cost of maintenance in a workhouse has also increased. My right hon. friend cannot undertake to introduce a Bill for the purpose suggested in the last part of the question.

The Question of Attributability.

Mr. Lansbury asked the Minister of Pensions whether the fundamental principle of the royal pensions warrant, referred to in the Minister's answer on Dec. 14th last, prevented pensions being granted to men classified into grades lower than Grade A by doctors acting under the Compulsory Military Service Acts, but also certified as fit to serve at home or abroad; and whether the fundamental principle referred to also precluded the Minister from undertaking the onus of proof in those cases where there is any doubt as to the cause of a man's disability, so that a man classified in whatever category as fit for service either at home or abroad, and taken into the army as such, would be entitled to a pension unless the Minister or his officials could prove that the claim had been forfeited.—Major Tryon replied: The answer to the first part of the question is in the negative. As regards the second part of the question, it is the case that wherever a man has been invalided from the service my department accept the presumption that his disability is due to or aggravated by service, unless the balance of probability is against the man. On the other hand, in the case of a man who is not discharged from service on the ground of disablement, but who subsequently claims to be disabled by or in consequence of war service, it is clearly incumbent upon the man to produce some prima facie evidence in support of his claim. None the less, it is the practice of my department, in these as in all other cases, to assist the man in every way to establish his claim.

A Pamphlet on Vaccination.

Mr. Sullivan asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether his attention had been drawn to a statement that the Ministry had published a pamphlet in which the compulsory revaccination laws which existed in Prussia since 1834 were attributed to the year 1874, that being the year in which the Prussian laws were re-enacted for the new German Empire, thus concealing the fact of a serious outbreak of small-pox under conditions of strict vaccination; and whether this pamphlet, which drew a deduction in support of vaccination from inaccurate or misleading data, would be withdrawn.—Sir W. Joynson-Hicks replied: I am advised that the statement contained in the pamphlet to which the hon. Member refers is correct. The Prussian law of 1834 related only to soldiers in the Prussian army. Compulsory revaccination for the civil population in Prussia and the rest of the German Empire was first enacted in 1874. There is, therefore, no ground for suggesting that the pamphlet should be withdrawn.

MONDAY, FEB. 26TH.

Exports of British Morphia.

Mr. Gilbert asked the President of the Board of Trade the amount and value of British-made morphia which was exported in the years 1920, 1921, and 1922 respectively, and the countries to which these exports were consigned.—Mr. Bridgeman (Home Secretary) replied: The statistics of exports for 1922 are not yet ready, but I will give the information for 1920 and 1921 so far as it is available:—

The following statement has been prepared by H.M. Customs and Excise, and shows the quantity of morphia and morphia salts registered as exported from the United Kingdom during the year 1920, distinguishing the principal countries of destination:—

	lb.		oz.
Russia	331	=	5,296
Sweden	1,685	=	26,960
Germany	666	=	10,656
Belgium	1,943	=	31,088
France	9,547	=	152,752
Macao	—		—
Japan (including Formosa, and Japanese leased territories in China)	1	=	16
United States of America	1,028	=	16,448
Other Foreign Countries	3,829	=	61,264
Total to Foreign Countries ..	19,030	=	304,480
Hong-Kong	1	=	16
Canada	796	=	12,736
Other British Possessions	327	=	5,232
Total to British Possessions ..	1,124	=	17,984
Total	20,154	=	322,464

N.B.—(1) These figures also include quantities of heroin and heroin salts, which cannot be given separately.

(2) These figures do not include exports by parcel post of which no record has been kept by the Customs Department, nor do they include exports of preparations containing the drug.

[The statement from H.M. Customs and Excise contained also the figures of morphine and morphine salts exported during 1921, distinguishing the countries of destination, and prepared from the returns of exporters licensed under the Dangerous Drugs Act.]

TUESDAY, FEB. 27TH.

Women Visitors of Lunatic Asylums.

Mr. Burgess asked the Secretary for the Home Department whether there were any women visitors of lunatic asylums; and whether the supervision of male lunatics was conducted by women or men.—Sir W. Joynson-Hicks replied: There are women visitors to lunatic asylums in cases where women are members of the visiting committee. The supervision of male patients is not conducted by women, but in some institutions suitable male patients are nursed by women, and this would generally be the case in the infirmary wards.

Anthrax in East Indian Wool.

Mr. Turner asked the Secretary for the Home Department what special steps, if any, were being taken to deal with the prevention of anthrax arising from the use of East India wools in the mills of the heavy woollen districts.—Mr. Bridgeman replied: The use of East Indian wool is subject to regulations made under the Factory and Workshop Act.

As being material which is liable to be infected with anthrax there is power also to deal with it under the Anthrax Prevention Act, 1919; but as the hon. Member will be aware the disinfecting station at Liverpool was designed in the first instance on a small scale as a trial station to test the practical working of the process of disinfection, and the quantities of East Indian wool imported are greatly in excess of the capacity of the existing plant. It will not be possible, therefore, to apply the Act until the station can be extended; but pending such extension the disinfection of such wools sent voluntarily is undertaken so far as the capacity of the station permits.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, March 5th.

TROPICAL DISEASES AND PARASITOLOGY: at 8.30 P.M.
Laboratory Meeting at the London School of Tropical Medicine, 23, Endsleigh-gardens, N.W.1.

Tuesday, March 6th.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)
Discussion: On the Operative Treatment of Spastic Paralysis, to be opened by Mr. A. S. Blundell Bankart.
Those intending to take part in the Discussion will be furnished with an abstract of the opening paper on application to the Hon. Secretary, Mr. Gordon Pugh, Queen Mary's Hospital, Carshalton.
Cases, particularly those illustrating the subject of the Discussion, will be welcomed at 5 P.M.

NEUROLOGY: Members of this Section are specially invited to attend the above meeting, and take part in the Discussion.

Wednesday, March 7th.

SURGERY: at 5.30 P.M.
Paper:
Sir G. Lenthal Cheatle: The Sites of Origin and Methods of Growth of Fibro-Adenomata of the Breast.
Demonstration:
Dr. Ernest H. Shaw: The Immediate Microscopic Diagnosis of Tumours at the Time of Operation.
Specimens:
Mr. Frank Kidd: A Specimen of Spindle-Celled Sarcoma arising in the Mesentery of a Coil of Ileum successfully removed at operation.
Mr. Cecil Rowntree: Three specimens of Sarcoma of the Small Intestine.

Thursday, March 8th.

BALNEOLOGY AND CLIMATOLOGY: at 5 P.M.
Discussion:
Dr. C. F. Sonntag will open a Discussion on the Vagus and Sympathetic Nerves and their Relation to Climate and Hydrology. Sir William Bayliss, Dr. Langdon Brown, Dr. F. G. Thomson, Dr. Calthrop, Dr. L. Schmidt (Postyen, Czecho-Slovakia), and Dr. J. Campbell McClure will take part.
Members of other Sections are cordially invited to be present and join in the Discussion.
Members of the Section, with guests, will dine together at the Welbeck Palace Hotel, Welbeck-street, W. 1, at 7.30 P.M. Those intending to be present are requested to inform Dr. Sonntag, 80a, Belsize Park-gardens, N.W. 3, not later than by the last post on March 7th.

NEUROLOGY: at 8.30 P.M.
Discussion on the Treatment of Neuro-Syphilis, to be opened by Dr. Farquhar Buzzard and Dr. Henry MacCormac.

Friday, March 9th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)
Cases will be shown.

OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)
Papers:
Mr. Humphrey Neame: Tumours of Optic Nerve.
Mr. Williamson-Noble: Orbital Endotheliomata.
There will be no meeting of the Section in April, owing to the proximity of the Annual Meeting of the Ophthalmological Society of the United Kingdom.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
Wednesday, March 7th.—9 P.M., Second Lettsomian Lecture. Mr. W. E. Miles: Carcinoma of the Rectum.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.
Tuesday, March 6th.—5 P.M., First Goulstonian Lecture:—Dr. G. Evans: The Nature of Arteriosclerosis.
Thursday.—5 P.M., Second Goulstonian Lecture.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
Monday, March 5th.—5 P.M., Hunterian Lectures on Man's Posture: its Evolution and Disorders: Prof. Sir A. Keith. Lecture I.
Wednesday.—5 P.M., Lecture II.
Friday.—5 P.M., Lecture III.

FELLOWSHIP OF MEDICINE, POST-GRADUATE LECTURES, 1, Wimpole-street, W.
Wednesday, March 7th.—8.30 P.M., Dr. G. Riddoch: Diagnosis and Treatment of Cerebral Syphilis.
(At the Western General Infirmary, Marylebone-road, N.W.)
Monday, March 5th.—Prof. Sir Wm. Bayliss: The Use of Saline Injections in the Treatment of Disease.

WEST END HOSPITAL FOR NERVOUS DISEASES.
The following Clinical Demonstrations will be held during the forthcoming Session in the Out-patient Department of the Hospital, 73, Welbeck-street, W. The Demonstrations are open to Practitioners and Medical Students without fee.
Tuesday, March 6th.—2 P.M., Mr. Laming Evans: Orthopædic Treatment of Nervous Diseases.
Friday, March 9th.—4.30 P.M., Sir James Purves-Stewart: Clinical Cases. C. Worster-Drought, M.D., Dean.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: Jan.–March, 1923.

Clinical Lectures and Demonstrations.

Monday, March 5th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Clinical Lecture:—Dr. Aldren Turner.
Tuesday, March 6th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Head Injuries: Mr. Armour.
Thursday, March 8th.—Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Lecture:—The Electrical Testing of Muscles: Dr. Bailey.
Friday, March 9th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Cervical Ribs: Mr. Sargent.
Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

Neuro-Pathology.

Monday, March 5th.—12 noon, Syphilis of the Nervous System: Dr. J. Godwin Greenfield.

N.B.—A Course of Lectures in the Anatomy and Physiology of the Nervous System will be given if there are sufficient entries for it.

The fee for the whole Course, including Anatomy and Physiology, is £12 12*s.*; but these Lectures may be taken separately for a fee of £4 4*s.* Course without Anatomy and Physiology Lectures will be £10 10*s.* Any part of the Course may be taken separately at a special fee. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.
C. M. Hinds Howell, Dean of Medical School.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
Monday, March 5th.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.
Tuesday.—10.30 A.M., Dr. Paterson: Demonstration of Medical Cases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.
Wednesday.—11 A.M., Mr. Simson: Gynæcological Demonstration. 12 noon, Dr. Burnford: Pathological Demonstration. 4 P.M., Dr. Pernet: Syphilitic Affections of Skin in Infants and Children.
Thursday.—10 A.M., Dr. Grainger Stewart: Neurological Department. 12 noon, Mr. Simmonds: Demonstration of Fractures. 4 P.M., Dr. Snowden: Relation between Anxiety States and Toxæmia.
Friday.—12 noon, Dr. Flett: Radiology. 2 P.M., Mr. Banks-Davis: Diseases of Throat, Nose, and Ear. 3 P.M., Mr. Sinclair: Surgical Cases.
Saturday.—9 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10.30 A.M., Mr. Maingot: Surgical Pathology.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON CLINICAL SOCIETY, Prince of Wales's General Hospital, S. Tottenham.
Wednesday, March 7th.—8 P.M., Dr. F. Tresilian: Cases from General Practice (Discussion and Cases).

UNIVERSITY OF LONDON ADVANCED LECTURES IN MEDICINE, Robert Barnes Hall, Royal Society of Medicine, 1, Wimpole-street, W.
(Course of Three Free Lectures.)
Wednesday, March 7th.—5.30 P.M., Sir Archibald E. Garrod: Alcaptonuria and Ochronosis. (Second Lecture.)

UNIVERSITY COLLEGE, Gower-street, W.C.
(Course of Three Public Lectures in the Physiology Theatre.)
Wednesday, March 7th.—5 P.M., Mr. A. H. Drew: The Cultivation of Tissues in Vitro. (Second Lecture.)

LONDON HOSPITAL MEDICAL COLLEGE, Mile End, E.
(In the Anatomical Theatre.)
Thursday, March 8th.—5 P.M., Dr. J. H. Sequeira: Advances in the Treatment of Skin Disease by Light.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.
Monday, March 5th.—4.30 P.M., Dr. T. Grainger Stewart: Demonstration of Neurological Cases.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street.
Thursday, March 8th.—4 P.M., Dr. Shires: X Ray Diagnosis of Diseases of the Chest.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, W.
Thursday, March 8th.—5.30 p.m., Dr. F. W. Price: Cardiac Arrhythmias.

HARVEIAN SOCIETY OF LONDON (Town Hall, Paddington).
Thursday, March 8th.—8.30 p.m., Dr. W. Hunter: Septic Anæmias.

MANCHESTER CLINICAL SOCIETY, Onward Buildings, Deansgate.
Thursday, March 8th.—4.30 p.m., Dr. Robert Hutchison: The Chronic Abdomen.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
Tuesday, March 6th.—4.15 p.m., Dr. W. F. Shaw: Treatment of Uterine Fibroids.
Friday.—4.15 p.m., Dr. E. M. Brockbank: The Microscopical Examination of Blood in Diagnosis of Disease.

ANCOATS HOSPITAL POST-GRADUATE LECTURE.
Thursday, March 8th.—4.30 p.m., Mr. P. G. McEvedy: The Diagnosis of Tuberculous Peritonitis.

ST. MARY'S HOSPITALS, MANCHESTER. POST-GRADUATE LECTURE (Whitworth-street West Branch).
Friday, March 9th.—4.30 p.m., Dr. Lacey: Treatment of Obstetric Emergencies.

MANCHESTER BABIES' HOSPITAL, POST-GRADUATE LECTURES, Slade-lane, Levenshulme.
Saturday, March 10th.—4 p.m., Dr. Catherine Chisholm: Discussion on the Various Methods of Arranging and Calculating Cows' Milk Feeds.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
Wednesday, March 7th.—4 p.m., Major A. T. Frost, R.A.M.C.: Venereal Disease under Army Organisation.

Appointments.

Archer, G. E., M.B., Ch.B. Manch., has been appointed Honorary Surgeon in Charge of the Ear, Nose, and Throat Department, Stockport Infirmary.

Baldwin, C. W. T., M.R.C.S., L.R.C.P.Lond., Assistant Radiologist (Therapeutic) to the Middlesex Hospital.

Goodwin, A., M.D. Lond., F.R.C.S. Eng. & Edin., Assistant Gynæcologist to the Prince of Wales General Hospital, Tottenham.

Jephcott, Charles, M.B., B.Ch.Camb., M.R.C.S., L.R.C.P. Lond., Police Surgeon for the City of Chester.

M'Clure, I. H., M.B., Ch.B. Edin., Resident Surgeon, Royal Surrey County Hospital, Guildford.

McCullagh, A. C. H., M.D. Durh., to be one of the Medical Referees under the Workmen's Compensation Act, 1906, for County Court Circuit No. 2.

Pickworth, F. A., M.R.C.S., L.R.C.P. Lond., Assistant Pathologist in connexion with the Joint Board of Research for Mental Diseases, City of Birmingham.

St. Thomas's Hospital: Story, A. G., M.R.C.S., L.R.C.P.Lond., Cole, L. B., M.B., B.Ch. Camb., Gibson, C. P. R., M.R.C.S., L.R.C.P. Lond., Fuller, C. B. S., M.B., B.Ch.Camb., Sudbury, F. B., M.R.C.S., L.R.C.P.Lond., Davies, D. A., M.R.C.S., L.R.C.P.Lond., Hughes, K. E. A., M.R.C.S., L.R.C.P. Lond., Crockford, A. L., M.B., B.Ch. Camb., Casualty Officers and Resident Anæsthetists; Gaydon, F. A., M.R.C.S., L.R.C.P.Lond., Bain, C. W. C., M.B., B.Ch.Oxf., Leys, D. G., M.B., B.Ch.Oxf., Oliver, C. P., M.R.C.S., L.R.C.P.Lond., Resident House Physicians; Phillipps, F. A., M.R.C.S., L.R.C.P.Lond., Resident House Physician (for Children); Macpherson, N. S., M.R.C.S., L.R.C.P.Lond., Patrick, C. V., M.R.C.S., L.R.C.P.Lond., Nichol, R. W., M.R.C.S., L.R.C.P.Lond., Churcher, J. C., M.R.C.S., L.R.C.P.Lond., Resident House Surgeons; Lund, G. S., M.R.C.S., L.R.C.P.Lond., Resident Orthopædic House Surgeon; Williams, E., M.R.C.S., L.R.C.P.Lond., Neilson, D. F. A., F.R.C.S.Eng., Resident House Surgeons for Ear, Nose and Throat; Slaughter, H. L., M.R.C.S., L.R.C.P.Lond., Senior Obstetric House Physician; Smalley, L., M.R.C.S., L.R.C.P.Lond., Junior Obstetric House Physician; Gough, J. H. H., M.R.C.S., L.R.C.P.Lond., Senior Ophthalmic House Surgeon; Doggart J. H., M.R.C.S., L.R.C.P.Lond., Junior Ophthalmic House Surgeon; Cavenagh, J. B., M.B., B.Ch.Oxf., Naude, A. L. te. W., M.R.C.S., L.R.C.P.Lond., Franklin, C. A. H., M.R.C.S., L.R.C.P.Lond., Slater, A. E., M.R.C.S., L.R.C.P. Lond., Kies, J. P., M.R.C.S., L.R.C.P.Lond., Allen, H. S., M.R.C.S., L.R.C.P.Lond., French, L., M.R.C.S., L.R.C.P. Lond., Lawn, L., M.R.C.S., L.R.C.P.Lond., Page, E. S., M.R.C.S., L.R.C.P.Lond., Morrison, R. G., M.R.C.S., L.R.C.P.Lond., Thomson, T. R., M.R.C.S., L.R.C.P.Lond., Facey, R. V., M.R.C.S., L.R.C.P.Lond., Curwen, E. C., M.R.C.S., L.R.C.P.Lond., Swan, G. R. M., M.R.C.S., L.R.C.P.Lond., Palmer, H.M., M.R.C.S., L.R.C.P.Lond., Clinical Assistants.

Certifying Surgeons under the Factory and Workshop Acts: Burns, A. S., M.B., Ch.B. Ed. (Chapel-en-le-Frith District of the County of Derbyshire); Robinson, J. (Canterbury).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary Treatment Centre.—Jun. M.O. £500.
Ashington Hospital, Northumberland.—H.S. £200.
Ayr County Hospital.—Res. H.S. £175.
Barnet, Wellhouse Hospital.—Asst. Res. M.O. £150.
Birmingham Orthopædic Centre.—Jun. M.O. £350.
Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H.S. £175.
Bolingbroke Hospital, Wandsworth Common, S.W.—Radiologist.
Cardiff City.—Asst. M.O. £550.
Carlisle, Cumberland Infirmary.—R.M.O. £175.
Cheadle, Cheshire, Cheadle Royal.—Asst. M.O. £350.
Derby County Mental Hospital, Mickleover.—Jun. Asst. M.O. £350.
Eastbourne, Princess Alice Memorial Hospital.—Hon. M.O. for Radiological and Electro-Therapeutic Department.
East Ham County Borough.—Female Asst. M.O. £500.
Exeter, Royal Devon and Exeter Hospital.—Sen. H.S. and Asst. H.S. £250 and £150 respectively.
Freemasons' Hospital and Nursing Home, 237, *Fulham-road, S.W.*—Res. M.O. £250.
French Hospital and Dispensary, 172, *Shaftesbury-avenue, W.C.*—Hon. Dental Surgeon.
Harrogate Infirmary.—Res. H.S. £150.
Hastings, East Sussex Hospital.—Hon. Asst. S.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S., H.P., and Asst. Cas. O. Each £50.
Leeds Public Dispensary.—Jun. Res. M.O. £150.
London Lock Hospital, 91, *Dean-street, W.*—H.S. £200.
London (Royal Free Hospital) School of Medicine for Women, Hunter-street, W.C.—Sec. Asst. in Obstetrical and Gynæc. Unit. £500.
London Temperance Hospital, Hampstead-road, N.W.—H.P. £120.
Manchester, Ancoats Hospital.—R.M.O. £200. Med. Reg. £100. H.S. £100.
Manchester City.—Female M.O. £632 7*s.* 8*d.*
Maudesley Hospital, Denmark Hill, S.E.—Pathologist. £1000.
Newcastle-upon-Tyne Hospital for Sick Children.—Sen. and Jun. R.M.O.'s. £170 and £140 respectively.
North Middlesex Hospital, Edmonton, N.—Asst. M.O. £200.
Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £150.
Oldham Union Poor-law Institution, Rochdale-road.—Res. Asst. M.O. £300.
Queen Mary's Hospital for the East End, Stratford, E.—Hon. Asst. Surg.
Royal Chest Hospital, City-road, E.C.—Res. M.O. £200. Also H.P. £120.
Royal Free Hospital, Gray's Inn-road, W.C.—Second Ven. Dis. Asst. £100.
Royal Northern Hospital, Holloway-road, N.—M.O. to Out-patients. £150. H.P. and H.S. Each £100. Surgeon for Diseases of Ear, &c.
St. Mary's Hospital for Women and Children, Plaistow, E.—Res. M.O. £175.
St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C.—H.S. £75.
Salford Royal Hospital.—H.P. £200. H.S. and Cas. H.S. £150 each.
Sheffield, South Yorkshire Asylum.—M.O. and Pathologist. £400.
South Shields, Ingham Infirmary.—Jun. H.S. £150.
Stanmore, Middlesex, Royal National Orthopædic Hospital, Brockley Hill.—Hon. Dental S.
Sunderland Children's Hospital.—Jun. Res. M.O. £100.
Sunderland Royal Infirmary.—H.P. £160. H.S. £160.
University College Hospital Medical School, University-street, W.C.—Asst. to Professor of Pathology. £500.
University of London.—Chair of Anat. (tenable at St. Bart.'s Hosp. Med. Coll.). £1000.
West End Hospital for Nervous Diseases, Regent's Park, N.W.—Jun. H.P. £100.
West London Hospital, Hammersmith-road, W.—H.P. and Two H.S.'s. Each £100.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointment: Alnwick (Northumberland).

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, 1906, for County Court Circuit No. 17, attached more particularly to the Boston, Holbeach, Sleaford, Spalding, and Spilsby County Courts.

Births, Marriages, and Deaths.

BIRTHS.

Allport.—On Feb. 25th, at Palace Gardens-terrace, W., the wife of Alfred Allport, M.R.C.S., of a son.

Salt.—On Feb. 18th, at Chirk, North Wales, the wife of Charles E. Salt, M.B., Ch.B., of a daughter.

Skirving.—On Feb. 23rd, at Rothesay-place, Edinburgh, the wife of A. A. Scot Skirving, C.M.G., F.R.C.S. Edin., of a son.

DEATHS.

Denholm.—On Feb. 19th, at Putney, London, Andrew Denholm, M.D., late of Duddington, Edinburgh, and Chorlton-cum-Hardy, Manchester, in his 72nd year.

Haslam.—On Feb. 27th, at 8, Vicarage-road, Edgbaston, Amy, wife of William F. Haslam, M.B., F.R.C.S.

Howden.—On Feb. 24th, suddenly, Ian Dalrymple Clark Howden, M.D., F.R.C.S. Edin., of Cambridge-terrace, Dover.

Smith.—On Feb. 21st, suddenly, Peter Caldwell Smith, C.B.E., M.A., M.D., Lieut.-Colonel, R.A.M.C., T., Medical Officer of Health for Wandsworth Borough, aged 64.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

A NATIONAL APPEAL FOR REFUGEES IN THE NEAR EAST.

AN opportunity has now arisen for relief work on a reconstructive basis in connexion with the problem of the Near Eastern refugees, and an all-British appeal for funds to support this object is made by the Imperial War Relief Fund, the Save the Children Fund, and the Friends' Relief Committee. The Greek Government have allotted a district of land to about 10,000 refugees, and have supplied such building materials, agricultural implements, tools, &c., as will enable the latter to build their villages and settle permanently on the land. Food supplies which will last till the beginning of April are already in hand, but the interval between that date and the gathering of the harvest is unprovided for. The High Commissariat of the League of Nations has requested the assistance of the British relief organisations to complete and extend this work of permanent relief. The Greek Government has given assurance of the supply of essentials which will enable the refugees in this area to become self-supporting after the harvest is gathered; the relief societies associated in the all-British appeal, who are already feeding 35,000 refugees in other parts of Greece, have agreed to provide the necessary food, which will be distributed under British supervision; and, in view of the serious outbreak of epidemics, the British Red Cross Society have consented to take over and enlarge the hospital established by Lady Rumbold, and to administer medical relief over the whole of this area. The appeal is signed by the Prime Minister, the Archbishops, and other political and religious leaders. Donations, which may be earmarked, if desired, for general relief purposes or for medical relief, will be gladly received by the Lord Mayor of London, Mansion House, London, E.C. Letters should be marked "Near East Appeal."

PUBLIC HEALTH IN BRITISH HONDURAS.

Lieut.-Colonel Max Smith, Colonial Secretary of British Honduras, in a report for 1921–22, states that the outstanding feature of the year, as regards public health and sanitation, was an outbreak of yellow fever. This occurred in August, 1921, at Loyola Park, a Roman Catholic college situated about a mile from the town of Belize, and having at that time over 100 local day scholars and about the same number of boarders drawn mostly from Guatemala, Honduras, Mexico, and San Salvador. Three suspicious cases were reported by the college physician and were diagnosed the same day by Dr. Gann, P.M.O., as yellow fever. They were immediately removed to the hospital, where they died the same evening, the autopsy fully confirming the diagnosis. The next day two more cases were reported, and from August 19th to 25th 14 cases in all occurred. This proved to be a secondary infection. The first case developed on August 14th, so there must have been one or more infected mosquitoes at some date prior to July 29th. This corresponds to the time when the boarders were returning from their vacation. Yellow fever, therefore, was undoubtedly introduced from outside, as no case had occurred in the colony since 1905. In 1920 and 1921 it was prevalent in Guatemala and San Salvador, and it still exists in Mexico. Probably an ambulatory case arrived amongst the boys so slight as to be unrecognised. The authorities took prompt action. The college was quarantined and the buildings fumigated, but as further cases occurred the whole of the inmates were removed to an isolation station on one of the islands, with the result that no more cases occurred and all were returned on Sept. 23rd. Three isolated cases occurred in Belize, the last on Nov. 13th. The infection undoubtedly reached the town and it is surprising that more cases did not occur amongst a large non-immune population, many of whom were particularly susceptible. That such did not occur was in the opinion of the P.M.O. due to the Noguchi vaccine which was supplied gratis by the Rockefeller Foundation and largely used, particularly amongst the susceptible class. The serum also undoubtedly reduced the death-rate amongst the sufferers. In response to an invitation by the Government two representatives of the Rockefeller International Board of Health arrived on Sept. 29th from Guatemala to assist in the preventive measures to be taken against the disease. An energetic campaign was at once commenced, with the result that the "house index" was reduced by the end of December to nearly the safety limit; but it is costly work and at the best of a temporary nature. Belize is swampy and has no natural drainage; it is entirely dependent on rain-water for its water-supply. The only permanent solution of the danger is an adequate pipe water-supply and the raising of the low-lying parts of the town—the latter of which will help to eradicate malarial fever. One of the greatest problems of the colony is how to banish malaria. It is the pivot on which all public health problems balance. Every industry and occupation is greatly handicapped by its ravages. As Dr. Wise, in writing of British Guiana, says: "It is a blight on the land. People are poisoned with it at birth and live in infancy and childhood with a millstone around their necks." The untiring efforts to eradicate the stegomyia mosquito that carries the yellow fever germ have had some effect in reducing the breeding-places of the anopheles that convey malaria. The census taken in 1921 shows a population of 45,317—22,564 males and 22,753 females. The birth-rate for the year was 35·456 and the death-rate 24·507 per 1000 of the population. The principal causes of death in order of degree were diseases of the digestive system, followed by those of the respiratory system, and then by those classified under the genito-urinary system. Deaths from malaria gave a proportion of 10 per cent. of the total deaths, and tuberculosis accounted for 6·9 per cent. of all the deaths registered. The climate of British Honduras has the reputation of being a very unhealthy one, but facts show that it compares not unfavourably with that of other tropical countries with small European populations. Europeans leading a normal life and taking common precautions find the climate pleasant and healthy. The hottest day of 1921 was Sept. 5th, when the thermometer registered 88° F., and the coldest, Jan. 29th, 58°. The total rainfall at Belize was 85·92 inches. The colony is outside the track of hurricanes, and earthquakes are unknown. From October to January cool northerly winds blow at times.

HOW TO WRITE A MEDICAL PAPER.[1]

A GOOD deal of information has been given at different times by societies and associations, by editors, and by experienced authors, as to the writing of medical papers, and some of these instructions or compilations of advice have contained disquisitions which, however true, had little to do with the subject. The Editor of the Mayo Clinic Publications keeps severely to the point. Her 20 little chapters are excellent examples of her own rules with regard to arrangement, for each chapter states clearly its subject, begins promptly, and ends by bringing the arguments to a climax. It is not until we read the mass of detailed instructions, of recommendations, and of "Dont's," which are here brought together, that we realise how much the writer of a medical paper has to think of, if he is to tell his story or deliver his message clearly and accurately as well as grammatically. He has to follow accepted style in many details, while providing a properly revised essay with references verified and with the tabular matter rightly used. This is not at all easy. The small book is intended to help untrained and partly trained writers to prepare for publication articles that will convey information with brevity, accuracy, and clearness. We may say that the intention has been quite successful; many writers who are not untrained, and who are avowedly literary in their avocations, to say nothing of busy clinicians, will find useful information in this practical little work. Here and there the advice only applies to our American colleagues.

THE LEWBART DISINFECTOR.

WE have recently had the opportunity of inspecting the construction and working of the Lewbart disinfector, an ingenious device which, fixed to the flushing pipe of a water-closet cistern, admits of automatic disinfection of the pan after flushing, in such a way that seven ounces of water mixed with disinfectant is left standing in the pan. The chief defects of disinfectant devices in the past have been (*a*) that contrivances fitted to discharge disinfecting fluid into the cistern itself require large quantities of disinfectant and destroy the cistern by corrosion, and (*b*) that contrivances whereby disinfectant, unmixed with water, is introduced through small tubes are unsatisfactory, in that the tubes rapidly become choked, and that it is difficult to determine whether the apparatus actually contains disinfectant at any given time. The Lewbart disinfector discharges its disinfectant already mixed with water into the pipe after flushing, so that the disinfectant is not carried into the drain until the next flush; the device is nickel-plated, having nothing to be corroded. Moreover, the mixing takes place in sight, behind a glass panel, so that if the water does not become discoloured it is at once apparent that the disinfectant container above it is empty.

The chief claim made on behalf of the device is that it dispenses almost entirely with the human element; each time the chain is pulled the downrush of water depresses a lever, —as it were a trigger reaching into the pipe—which releases 5 minims of disinfectant into the mixing chamber; 7 oz. of the descending water is captured in the chamber, mixed with disinfectant, and passed out again into the cistern pipe. The human element, indeed, is restricted to the slight trouble of fixing the device—which can be done by anyone with a penknife and a screwdriver—and the necessity, occurring once in about three months in a private house, of purchasing a new container at a chemist's or ironmonger's.

---

[1] The Writing of Medical Papers. By Maude H. Mellish, Editor of the Mayo Clinic Publications. London and Philadelphia: W. B. Saunders Company. 1922. Pp. 157.

The Lewbart disinfector was first introduced in South Africa, where it has won much approval from Government and municipal authorities, and private firms and individuals. It is claimed to have played a large part in the recent reduction of the incidence of dysentery in large South African towns. The disinfector is owned by the Lewbart Manufacturing Co., Ltd., of 2 and 3, Norfolk-street, Strand, London, W.C., from whom any further particulars can be obtained. It is sold retail at 35*s*.

THE ERRORS OF SPIRITUALISM.[1]

WE have received an earnest little book by Mr. James Gillingham, a surgical mechanician, in which he points out the dangers inherent in the superstitions of spiritualism. The book is written in a spirit of fervent Christianity, and the doctrines of spiritualism are stated to be the wisdom of Satan at the head of a vast principality in rebellion against God. The application of this fundamental tenet to all the manifestations of the occult with which modern life has made us familiar gives rise to positions that are distinctly piquant.

THE CHAULMOOGRA PLANT IN LEPROSY.

To the Editor of THE LANCET.

SIR,—I am sorry that Dr. G. C. Kusumbeker should have thought it worth while to question in your issue of Feb. 3rd the truthfulness of the pretty legend I related about the use of the chaulmoogra plant in leprosy in olden times and the love affairs of King Rama and Princess Piya associated therewith, communicated to THE LANCET of Jan. 13th. I did not vouch for the authentic veracity of the story and I should have been as indisposed to enter upon a critical analysis of it as I should to inquire into the truthfulness of Grimm's Fairy Tales or the fables of our old friend Æsop. Such stories lose much of their innocent pleasure and charm when dissected. A very wise and ancient king has placed on record in one of the most ancient and sacred books that there is nothing new under the sun.

I can, however, bear testimony to the fact that chaulmoogra oil was used as an external and internal remedy in leprosy over 45 years ago in the Medical College Hospital of Calcutta. My friend and talented teacher, the late Lieut.-Colonel Edward Lawrie, I.M.S., when resident surgeon of that institution as far back as 1877 used chaulmoogra oil in the out-patient department in the treatment of these cases, a certain quantity being given internally (so far as I can remember as an emulsion with lime-water) and externally as a liniment at the same time. Opinions regarding the efficacy of this treatment were expressed with much reserve.

I am, Sir, yours faithfully,
P. HEHIR,
Major-General, I.M.S. (retd.).

Athens, Greece, Feb. 14th, 1923.

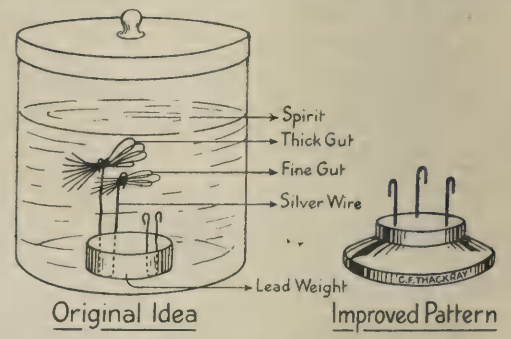
MOSQUITO MISÈRE.

IF anyone wishes to learn how miserable life may be in the tropics with only rudimentary sanitation, or to get some idea what life was in the tropics for the old-time pioneers before tropical medicine had been developed by Ross and others, when people had to live among perennial swamps teeming with unprevented mosquitoes, he cannot do better than read Captain C. C. G. Gibson's article in the *Journal of the Royal Army Medical Corps* for January describing the experiences of 250 men of the Royal Sussex Regiment at Belize in 1919–20. The camp was at sea-level, and fortunately under the influence of the trade-wind which generally blew the mosquitoes away; but when the wind fell light these pests, and sand-flies too, swarmed, and in the hot, still, damp weather the atmosphere within an efficient muslin net was almost unbearable unless an electric fan could be fixed up inside. The barracks (wooden) were on piles, eight feet above the swampy ground, and had wire gauze windows and doors, but, owing to the holes and crevices in the warped woodwork, these screens only acted as traps to retain mosquitoes. In six months 57 per cent. of the detachment were attacked by malaria, usually, by the mercy of Providence, only mild benign tertian. During the calm weather many wore gloves and a towel or some other covering over the head and neck. "At night the men would congregate in the bathing sheds over the sea, where they would often be seen crying in their misery." This was within a thousand miles of the Panama Canal. In addition, the noise at night of the bull-frogs, crickets, croaking lizards, and other reptiles helped to banish sleep. The horses suffered badly from the mosquitoes, which gathered especially in the harness-room, so that the grooms could only do their work in an atmosphere of smouldering cocoa-nut husks which drove the insects away. It will be recalled that so long ago as 1750 Lind recommended that "smoak" should be made at night in hot countries to prevent fever. Mosquitoes, however, are not universally unpopular: spiders prefer them to flies, to eat.

A SILKWORM-GUT HOLDER.

To the Editor of THE LANCET

SIR,—The description of a simple and efficient silkworm-gut holder, which I gave in THE LANCET of Jan. 20th, is made clearer by reference to the accompanying diagram.



The advantages claimed are: 1. Each strand is delivered singly. 2. The gut is kept submerged in spirit. 3. One hand is left free for other work, the weight being sufficient to steady it. 4. Different gauges of gut are taken each in a distinct bundle. 5. The strands being picked up with forceps or a needle, contamination of the remaining pieces is prevented, thus is attained a more perfect degree of asepsis.

Messrs. C. F. Thachray, Leeds, have constructed the improved pattern for me.

I am, Sir, yours faithfully,
A. P. BERTWISTLE.

Leeds General Infirmary, Feb. 15th, 1923.

OPHTHALMOLOGICAL SOCIETY OF EGYPT: BULLETIN OF 1922.

THE report of the nineteenth annual meeting shows considerable activity in this Society. Sixty members out of a total membership of about eighty were present, and the bulletin contains as many as 22 short papers, mostly reports of cases. One of the most generally interesting is an account of a summer visit to the Vienna and Berlin Ophthalmic Clinics in 1921, by Dr. A. F. El Raschid Bey. Trephining for glaucoma, we learn, is nearly abandoned by most German operators now, owing to the danger of late infection. Iridectomy is the operation of choice, and where it fails, or in advanced cases, cyclo-dialysis is done. As a last resource for retinal detachment the trephine is used to make a $1\frac{1}{2}$ in. hole in the sclera over the detachment, after making a conjunctival flap and evacuating the subretinal fluid by the passage of a narrow Graefe knife through the choroid. Ionisation of the cornea is used to hasten the healing of corneal ulcers and the absorption of recent corneal opacities. A good deal of importance is attributed in Vienna to the treatment of various conditions by the intramuscular injection of boiled milk, especially in purulent ophthalmia. According to a lecture recently delivered by Prof. A. J. Clark the practice of non-specific protein therapy has in some quarters gone considerably beyond any theoretical justification for it, and we have not heard that milk injections for ocular disease have been much practised in England. Another paper in this bulletin by Dr. M. Tewfik advocates the treatment.

Dr. William McNiven Muat, senior medical officer, Wei-hai-wei, has been appointed C.B.E., Civil Division.

By Sir ALMROTH E. WRIGHT, M.D., F.R.S.

Part III.*

Résumé of the Conclusions reached in the Foregoing Inquiry.

We have seen that epiphylactic response can be evoked in the blood by vaccines; that it can be evoked both in vitro and in vivo; that it is characterised by a sudden increase in the bactericidal and opsonic power of the serum, and that this increase is the result of a sudden evacuation of polytropic bactericidins and opsonins from the leucocyte. We have learned also something—but of course nothing like all—of the conditions under which epiphylactic response can be obtained. We have seen that when we vaccinate a normal blood in vitro with dead microbes and then test it with living, and also when we test a patient's blood which has been acted upon by antigens in vivo, the event will depend upon the total of antigen which has been brought into operation in the vaccinating procedure or auto-inoculation on the one hand, and the assaying procedure on the other.

With respect to the causative nexus between the application of excessive doses of vaccines and the development of apophylactic effects there is still a very serious lacuna in our knowledge. Seemingly the apophylactic effects produced by staphylococcus vaccine are different in origin and kind from those produced by typhoid and cholera vaccine. Whereas typhoid and cholera exert their apophylactic effect when brought into contact with serum, staphylococcus vaccine operates apophylactically only when brought in contact with the whole blood. This would seem to warrant the inference that when staphylococcus vaccine reduces the anti-bacterial power of the blood it does so not by adsorbing anti-bacterial elements from the serum, but by inciting the leucocytes to excrete into the serum some growth-favouring element.

Let me—asking you to remember that I cannot do any justice to the subject in the space now left to me—briefly indicate to you to what uses it may be possible to put the new information now in our possession. We can put it to account in the first place in the preparation of bacterial vaccines.

Practical Applications.

Preparation and Control of the Efficacy and Dosage of Vaccines.

It will be clear that every point in connexion with the preparation of vaccines can be practically tested by the procedures that have been described above. For example, it will be possible to set on one side all those statistical inquiries which everyone proposes but nobody really carries out, and to ascertain directly whether one particular strain of microbes gives a better vaccine than another, whether one particular sterilising temperature is better than another, and whether it will be justifiable or unjustifiable to employ this or that particular vaccine in combating this or that infection. Further, we have here methods which will enable a comparison to be made between different kinds of vaccines. It will therefore henceforth be possible to call upon those who claim superiority for a particular brand of vaccine to show scientific justification for their claims. Lastly, it will be possible in the case of every vaccine to determine what is the dose which will give optimum response.

Here, however, we are launched upon a question which teems with difficulties and ambiguities. I will just indicate what they are and pass on. Consideration will show that when we speak of the optimum dose of a vaccine we really have in view a particular mode of administration and some approximate body weight (generally that of an average adult), and also a particular condition of the organism—the condition of being uninfected, or, as the case may be, lightly or heavily infected. Ordinarily, in speaking of the optimum dose, we have in view—and this is the particular point I wish here to consider—subcutaneous inoculation, this channel of administration being, upon the assumption that protective substances are formed in part at least by the tissues at the site of inoculation, regarded as the best. Doubts with regard to the trustworthiness of the premisses upon which this belief rests are suggested by two sets of facts recently brought to light. The first is that the implantation of sterile lint into the tissues gives precisely the same local yield of anti-bacterial substances as the implantation of lint impregnated with vaccines.[1] That points to the anti-bacterial substances coming not from the tissues but from some other element present in both cases, in other words, from the emigrated leucocytes; and to anti-bacterial substances being under these circumstances spontaneously set free from these. The second set of facts consist of those adduced above, which establish that bactericidal and opsonic substances are set free when vaccines in appropriate concentration come into operation upon leucocytes in the blood both in vivo and in vitro.

When these facts are regarded hypodermic inoculation stands out under a very different light. Its paramount advantage would appear to lie in the circumstance that the vaccine is under favourable circumstances fed slowly and continuously into the blood. But where a relatively large dose of vaccine is administered and carried into the blood too rapidly a formidable negative phase is bound to supervene. (It will be remembered that when the patient was not kept quiet after typhoid inoculation very severe negative phases used often to supervene.) And again, it will be clear that where a relatively small dose of vaccine is given and convection into the blood takes place very slowly, the quantum of antigen in the blood may never arrive at the concentration required for the production of epiphylactic response. These uncertainties—which would, of course, be exaggerated if the method of oral administration were followed—are avoided by the intravenous administration of a dose of vaccine standardised so as to give the optimum number of microbes per c.cm. of blood. With this system of dosage—which has here been followed throughout—there remain only the minor difficulties of estimating the patient's blood volume, and allowing for that progressive dissolution of microbes in the blood which might result in the bringing into application of more than the contemplated quantum of antigen. But these minor difficulties need not be too minutely insisted upon.

Extension of the Range of Therapeutic Inoculation.

We saw at the outset that ordinary vaccine-therapy had proved ineffective in chronic streptococcal septicæmias, in many of the acute septicæmic conditions of local origin, and in phthisis when associated with hectic temperatures. And it might have been added that vaccine-therapy has in pneumonia, in typhoid, and in other similar infections given either uncertain or negative results. For example, the inoculation of pneumococcus in native pneumonia patients in the hospitals of the Johannesburg mines[2] gave in our hands completely negative results. To the unsolved problems presented by this order of infections we must now return, asking ourselves whether we are still, as regards the actual treatment of the infection, compelled to make choice between a policy of non-intervention—disguised under the name of the expectant treatment—and a policy of purely empirical and ignorant intervention. The answer cannot be doubtful.

---

* The first and second parts of this lecture appeared in The Lancet of Feb. 24th and March 3rd respectively.

[1] Wright: Lessons of the War, The Lancet, March 29th, 1919, p. 496. The detailed experiments will be published subsequently.

To begin with—and this in itself constitutes a definite advance—we can now by a " vaccine-response test " undertaken upon the blood in vitro decide whether a patient is or is not capable of making immunising response. Where he is competent to make such response we can further ascertain to what dose of vaccine, intravenously inoculated, he will be able to make optimum response. In the alternative of his not being able to make immunising response to a vaccine we can straight off—for such cases do not admit of delay—evoke epiphylactic response in a healthy human blood and resort to what I have called immuno-transfusion. In addition to these therapeutic suggestions, which apply, as will be seen, to cases where life and death may already hang in the balance, two other proposals of perhaps lesser import may be brought up for consideration. The first relates to inhibitory inoculation in the incubation period of all zymotic fevers of bacterial or non-bacterial origin; the second relates to the possibility of arresting, even after they have declared themselves, those minor but incapacitating infections grouped together under the heading of common colds. When we regard the fact that a non-specific epiphylactic response can be evoked instantaneously by the intravenous inoculation of appropriate doses of vaccine, it is not too venturesome to suggest that these desirable objects might possibly be achieved.

Only a small part of the domain which has here been rapidly reconnoitred has yet been explored, so it will perhaps be better to defer for a further communication any detailed account of successes achieved and disappointments experienced. But it will be indispensable to explain the method of going to work upon cases of septicæmia and acute infection, and to show how the methods of blood examination which have been described above are to be used in connexion with these cases.

PROCEDURE TO BE FOLLOWED IN DEALING WITH CASES OF SEPTICÆMIA AND ACUTE INFECTION.

For the scientific treatment of any grave infection there is required before all an equipment of principles. But that does not suffice. One requires in addition specific information with regard to the patient's condition. We require to know how he stands in the matter of the anti-bacterial power of his blood, and in the matter of its capacity for making immunising response to vaccines. And it is also essential to ascertain by direct means, with regard to each therapeutic intervention in its turn, whether it has been useful or ineffectual or hurtful. The laboratory methods described above can furnish us with this information. The first point to consider is how the anti-bacterial power of the patient's blood is to be gauged. Here the slide-cell inculturing procedure, and another technique which I shall have to describe to you, furnish the required data.

SLIDE-CELL INCULTURING PROCEDURE FOR MEASUREMENT OF HÆMO-BACTERICIDAL POWER.

The following examples give an idea of what can be learned from the slide-cell procedure. It may be explained that in each case graduated dilutions of a broth culture of staphylococcus were implanted in to 50 or 100 c.cm. volumes of blood, and that the number of microbes implanted was enumerated by introducing similar quanta of suspension into serum and enumerating the colonies which developed in this after incubation in capillary tubes or slide-cells (vide supra, Figs. 2 and 3).

CHIASTIC PROCEDURE FOR MEASUREMENT OF PHAGOCYTIC POWER OF BLOOD, OPSONIC POWER OF SERUM, AND PHAGOCYTIC EFFICIENCY OF LEUCOCYTES.

What the slide-cell method supplies is, as has already been appreciated, a measurement of the hæmo-bactericidal power obtained with different additions of living microbes. It does not tell us anything about the different factors upon which hæmo-bactericidal power depends, nor does it, where a blood has a diminished bactericidal power, disclose to us the nature and reason of the default. A good deal of what is here left untold is supplied by the *chiastic method*. The procedure consists in preparing defibrinated blood from the patient and a normal man; separating the serum from each of the bloods; preparing from each washed corpuscles; and then making by what has come to be called the opsonic technique a series of four phagocytic mixtures, constituted as follows:—

(1) One volume of the patient's serum, 1 volume of his washed corpuscles, and 1 volume of any suitable bacterial suspension.

---

[2] Wright: On Pharmako-therapy and Preventive Inoculation Applied to Pneumonia in the African Native (Constable, London, 1914), pp. 83–85.

(2) One volume of the normal serum, 1 volume of the washed normal corpuscles, and 1 volume of the same bacterial suspension.
(3) One volume of the patient's serum, 1 volume of the normal corpuscles, and 1 volume of the bacterial suspension ; and
(4) One volume of the normal serum, 1 volume of the patient's corpuscles, and 1 volume of the bacterial suspension.

It is, of course, from the interchange and crossing of the corpuscles and sera in phagocytic mixtures 3 and 4 that the appellation *chiastic* is derived. The phagocytic mixtures having been incubated, spread out upon slides, and counted in the accepted manner, we now collate and marshal the results in the following fashion :—

(*a*) By dividing the phagocytic count (i.e., the average microbic intake) of preparation 1 by that of preparation 2 we obtain the *phagocytic index of the patient's blood.*

(*b*) By dividing the phagocytic count of preparation 3 by that of preparation 2 we obtain the *opsonic index of the patient's serum.*

(*c*) By dividing the phagocytic count of preparation 4 by that of preparation 2 we obtain the *phagocytic efficiency of the patient's leucocytes.*

A few examples will show clearly what we learn from this triad of phagocytic functions.

Example 1.—Surgical nurse with acute streptococcal infection originating from puncture in finger—temperature 105° F.

		P.C.
Patient's serum	+ patient's washed corpuscles + S.S. ..	0·57
Normal ,,	+ normal ,, ,, + ,, ..	3·9
Patient's ,,	+ ,, ,, ,, + ,, ..	2·6
Normal ,,	+ patient's ,, ,, + ,, ..	1·36

S.S. = Streptococcus suspension. (Here, and in all the subsequent cases, a streptococcus vaccine diluted suitably supplied the suspension employed.) P.C. = Phagocytic count.

Phagocytic index of patient's blood, 0·15 ; opsonic index of patient's serum, 0·65 ; phagocytic efficiency of leucocytes, 0·34.

Example 2.—Child, aged 3 years, with acute streptococcal infection and abscesses in joints and subcutaneous tissues.

		P.C.
Patient's serum	+ patient's washed corpuscles + S.S. ..	0·2
A. E. W.'s ,,	+ A. E. W.'s ,, ,, + ,, ..	1·3
Patient's ,,	+ ,, ,, ,, + ,, ..	1·75
A. E. W.'s ,,	+ patient's ,, ,, + ,, ..	0·18

Phagocytic index of patient's blood, 0·16 ; opsonic index of patient's serum, 1·3 ; phagocytic efficiency of leucocytes, 0·14.

Example 3.—Woman, aged 55 years, with streptococcal endocarditis.

		P.C.
Patient's serum	+ patient's washed corpuscles + S.S. ..	0·82
A. E. W.'s ,,	+ A. E. W.'s ,, ,, + ,, ..	4·05
Patient's ,,	+ ,, ,, ,, + ,, ..	0·44
A. E. W.'s ,,	+ patient's ,, ,, + ,, ..	0·12

Phagocytic index of patient's blood, 0·2 ; opsonic index of patient's serum, 0·1 ; leucocytic efficiency, 0·03.

Results such as these can be registered in all acute septic infections. The premonitory signs of a grave infection would seem to be a reduction of the leucocytic efficiency, coupled with a rise in the opsonic index, and, as a result of some counterbalancing of the two factors just mentioned, a moderate fall in the phagocytic index. That type of result comes quite regularly under observation when we add to the blood in vitro excessive quanta of vaccine. We have already seen examples, and shall see others when we deal with the vaccine-response test. In the later graver stages of an infection the opsonic power is also reduced, and then the whole triad of phagocytic functions is prejudicially affected until they all, as in the last example, stand very little above the zero point.

It may here be pointed out, with regard to the leucocytic efficiency, that it appears to be reduced with regard to all microbes indiscriminately. Further, it may be noted that the leucocytes can recover from this heavily-poisoned condition. They can, as will later be seen in an example, recover in vivo when the blood fluids which bathe them are rendered more wholesome ; and they can recover in vitro when transported into, and allowed to stand in, wholesome serum. What has been said above of the blood changes associated with acute sepsis may be completed by saying that the sero-bactericidal power is not even in grave infections sensibly reduced.

Investigation of the Patient's Power of Immunising Response.

When the anti-bacterial power of the blood has been investigated and been found wanting, the next thing to do is to find out whether the patient has any capacity of making immunising response, and with what vaccine and what dose he can make his optimum immunising response. This can be done by introducing graduated quanta of vaccine into a series of volumes of the patient's blood, and seeing whether there is any improvement in the hæmo-bactericidal or phagocytic power of the vaccinated bloods, or in the sero-bactericidal or opsonic power of their sera. The information being wanted almost immediately, and there being no time for culture, investigations of the bactericidal power are ruled out. We are therefore restricted to the measurement of the phagocytic power of the inoculated bloods and the opsonic power of their sera.

Let me show you in a series of examples what we can learn from phagocytic vaccine-response tests. I may with advantage consider, first, an example which comes from the bulletin of treatment of the child whose blood furnished a moment ago an illustration of the working of the chiastic procedure.

Blood of a child suffering from a generalised streptococcus infection and blood of a normal man who was about to furnish blood for immuno-transfusion into the child. March 7th, 1922, vaccine-response test conducted with defibrinated bloods.

—	Strepto-phagocytic indices.	
	Patient.	Proposed donor.
Blood unvaccinated	0·3	1·0
Blood vaccinated with 20 stc. per c.cm.	0·3	0·8
,, 40 ,, ,,	0·4	0·9
,, 80 ,, ,,	0·3	2·3
,, 160 ,, ,,	0·2	0·9

Stc. = streptococci.

Blood of a patient suffering from acute streptococcus infection with a mastoid suppuration and A. E. W.'s blood. Feb. 9th, 1922.

—	Strepto-phagocytic indices.	
	Patient.	A. E. W.
Blood unvaccinated	0·27	1·0
Blood vaccinated with 30 stc. per c.cm.	0·1	1·7
,, 60 ,, ,,	0·09	1·5
,, 90 ,, ,,	0·03	1·45
,, 600 ,, ,,	0·15	0·9

It is clear that when a patient's blood gives such results as these intravenous inoculations of vaccine are bound to do harm instead of good. These are cases for immuno-transfusion. The next example relates to the surgical nurse and to the self-same specimen of defibrinated blood which was employed for the first of the three chiastic tests cited above.

Patient with acute streptococcus infection spreading from a punctured wound and a temperature of 105° F.

The results recorded in the first column were obtained with phagocytic mixtures in which the sera and corpuscles of unvaccinated and vaccinated bloods were mixed with the streptococcus suspension ; the results in the second column were obtained with phagocytic mixtures in which the sera of the unvaccinated and vaccinated bloods were employed in combination with the corpuscles of normal blood.

Vaccine-Response Tests.

—	Strepto-phagocytic counts.	
	Blood.	Serum.
Blood unvaccinated	1·81	1·5
Blood vaccinated with 20 stc. per c.cm.	1·9	2·0
,, 40 ,, ,,	1·6	4·7
,, 80 ,, ,,	1·4	1·7
,, 160 ,, ,,	3·2	2·7

These results show (and the contrary might have perhaps been expected from the event of the chiastic test)[3] that the patient's blood still possessed a considerable capacity for immunising response, and that vaccination with 160 streptococci per c.cm. gave the best response. The patient was accordingly immediately inoculated intravenously with this dose of vaccine ; in other words, with 700,000 streptococci.

---

[3] Vide supra.

Patient with chronic streptococcic septicæmia and endocarditis.

Vaccine Response Test.

—	Staphylo-opsonic index.
Blood unvaccinated	1·0
Blood vaccinated with 20 strep. per c.cm.	1·12
,, ,, ,, 50 ,, ,,	1·18
,, ,, ,, 100 ,, ,,	1·6
,, ,, ,, 200 ,, ,,	1·4
,, ,, ,, 1000 ,, ,,	2·35
,, ,, ,, 4000 ,, ,,	1·26

This patient was obviously a suitable subject for intravenous inoculation with streptococcus vaccine.

VERIFICATION BY LABORATORY METHODS OF IMPROVEMENT OBTAINED IN GRAVE BACTERIAL INFECTIONS.

In grave bacterial infection only three kinds of therapeutic intervention appear to hold out any promise. (1) First among these would come—but the procedures in question apply only where there is localised infection —the evacuation of collections of infected pus, the effective draining of the tissues which encase a putrid wound, and the ablation of foci of infection. Such procedures, of course, put a quietus upon that continuous and immoderate auto-inoculation which poisons the leucocytes and interferes with immunising response. Where mechanical procedures for the reduction of the volume of infection are inapplicable our choice would appear to lie between (2) inoculations —by preference intravenous inoculations—of vaccine, and (3) immuno-transfusion. But our scientific task is not completed when we have applied the particular form of treatment selected. A priori inference is in medicine an untrustworthy guide. And when verification is in question, the guarantee furnished by quantitative laboratory methods—though this cannot perhaps vie with the psychological impression produced upon eye-witnesses by sudden and dramatic clinical improvement—is that which finally counts. In view of this I have set out below examples which show in connexion with each of the three aforementioned kinds of therapeutic intervention evidence of the benefit obtained from it. The examples have here been chosen to furnish illustration of points not previously brought out, and in particular to exhibit the increased anti-bacterial power obtained.

Example 1.—Showing the improved phagocytic and opsonic power and increased vaccine response and leucocytic efficiency obtained by evacuating an abscess.

Child with generalised streptococcus infection and an unopened abscess in the elbow joint who had been treated by two successive immuno-transfusions, each with 25 c.cm. of blood, on March 21st and 24th, 1922.

March 27th—*Chiastic Test:* Phagocytic index of blood, 0·07 ; opsonic index of serum, 0·8 ; phagocytic efficiency of leucocytes, 0·1. Abscess was now opened.

March 28th—*Chiastic Test:* Phagocytic index of blood, 1·02 ; opsonic index of serum, 1·4 ; phagocytic efficiency of leucocytes, 0·9.

Vaccine-Response Test.

	Strepto-phagocytic index.
Unvaccinated blood	1·0
Blood vaccinated with 20 strep. per c.cm.	1·3
,, ,, ,, 40 ,, ,,	1·6
,, ,, ,, 80 ,, ,,	1·0

To appreciate the improvement, the data of this vaccine response test should be compared with those registered with this child's blood before treatment was begun (vide foregoing section). The child's night temperature, which had for three weeks before the first immuno-transfusion ranged up to between 103° and 105°, and which had after the first immuno-transfusion come down to below 102°, and after the second to under 101° F., came down after the opening of the abscess to between 99° and 100° and soon after became normal.

Examples 2 and 3.—Showing increased phagocytic and opsonic power obtained by immuno-transfusion.

Patient with puerperal septicæmia. March 6th, 1922, immediately before immuno-transfusion, strepto-opsonic index 1·2, immediately after 2.

Example 3.—Patient with grave streptococcal infection and mastoid suppuration. Feb. 7th, immediately before immuno-transfusion, strepto-phagocytic index 0·3, immediately after 1·2. In this latter case the patient, who had three hours before the immuno-transfusion had a rigor with a temperature of 106° F., and was lying cyanotic and semicomatose, revived at once after the immuno-transfusion, the colour improving, the mental condition becoming normal, the patient remarking that she felt wonderfully better, eating ravenously, and sleeping quietly at night without requiring any administration of oxygen.

The same patient, after two further high evening temperatures. Feb. 9th, 1922, 24 hours before the second immuno-transfusion, strepto-phagocytic index 0·27 ; on the 10th, immediately before the immuno-transfusion, 0·0. Transfusion of blood vaccinated in vitro with 100 streptococci per c.cm. On the 11th, one day after, 0·7 ; on the 12th, two days after, 1·1. On the 14th, four days after, 1·3 ; on the 15th, five days after, 1·4.

Vaccine-Response Test. (This result is to be compared with that recorded in the previous section.)—On the 12th, unvaccinated blood per c.cm., strepto-phagocytic index 1·1 ; blood vaccinated with 20 streptococci per c.cm., 1·0 ; with 40, 1·3 ; with 80, 1·0.

In connexion with this immuno-transfusion the clinical report says : "The result of the transfusion was again magnificent, the oxygen inhalation being discontinued, while the patient's colour improved, and she took nourishment well and passed a very good night." After very slight rises of temperature treated by an inoculation of streptococcus vaccine the patient made a rapid recovery.

Example 4.—Showing the increased hæmo-bactericidal power obtained in the case of donor by the intravenous inoculation of 160,000 streptococci, and in the recipient by the immuno-transfusion of 500 c.cm. of the donor's blood, drawn off and defibrinated half an hour after intravenous inoculation.

Patient suffering from necrosis of frontal bone and generalised infection originating in an operation on the nasal sinuses. The slide-cell inculturing procedure was employed, graduated doses of staphylococci being implanted into 50 c.mm. volumes of blood.

Donor's blood.				Patient's blood.

Synopsis of Results.

1. Into the specimen of the donor's blood taken before inoculation in all 418 staphylococci were implanted, and 4·3 per cent. developed into colonies.

2. Into the sample of the donor's blood taken half an hour after inoculation in all 775 staphylococci were implanted and 1·3 per cent. developed into colonies.

3. Into the sample of the patient's blood taken immediately before immuno-transfusion in all 557 staphylococci were implanted and 14 per cent. developed into colonies.

4. In the sample of the patient's blood taken 24 hours after immuno-transfusion in all 366 staphylococci were implanted and 1·1 per cent. developed into colonies.

Comment.

In connexion with these and all other data furnished by the slide-cell inculturing procedure, it is perhaps advisable to return to a matter which has already been discussed, and to make clear the exact import of the figures. It must be kept in view that the assaying procedure employed is not an assaying procedure pure and simple, but also incidentally a supplementary vaccinating procedure. It follows that the improvement shown in the case of the donor is really the resultant of two vaccinations—a vaccination in vivo and a superadded vaccination in vitro—and in the same way the improvement shown in the case of the patient is the resultant of an immuno-transfusion in vivo and a superadded vaccination in vitro. That being so, we are not entitled to claim for the intravenous inoculation and the immuno-transfusion that it did all that the figures in the tables might at first sight suggest. But we shall have made the proper abatement from that claim if we say this: The bloods of the donor and patient respectively have been so improved by our operations that they would, if they afterwards encountered an infection equivalent to an implantation of in the one case 10,000 (496 × 20) or less staphylococci per c.cm., and in the other case to 3200 (164 × 20) or less staphylococci per c.cm., have shown an improvement equivalent to those set out in the tables in connexion with these figures.

Example 5.—Showing increased sero-bactericidal power obtained by immuno-transfusion of 500 c.cm. of defibrinated blood obtained from a donor who had four hours before been inoculated intravenously with 150,000 streptococci.

Patient suffering from a chronic hectic temperature supervening upon a staphylococcal infection of both breasts which had led to their amputation.

		Number of staphylococcus colonies which developed in 50 c.mm. volumes of serum.
Serum of blood drawn off	immediately before immuno-transfusion	36
	5 minutes after immuno-transfusion	28
	1 hour after immuno-transfusion	24

This is equivalent to an increased killing power of 240 staphylococci per c.cm. Consideration will show that this method of assay excludes the possibility of any supplementary epiphylactic response in vitro.

Example 6.—Showing increased sero-bactericidal power to staphylococcus obtained by the immuno-transfusion of 500 c.cm. of blood vaccinated in vitro with 30 streptococci per c.cm.

Patient with a chronic pyrexia following on a series of local streptococcal infections.

	Number of staphylococcus colonies which developed in 20 c.mm. volumes of serum.	
Serum from blood drawn 24 hours before immuno-transfusion	36 31	33½
Serum from blood drawn immediately before	44 36	40
Serum from blood drawn 5 minutes after transfusion	24 28	26
Serum from blood drawn 24 hours after transfusion	24 20	22

Calculation shows that here the serum after immuno-transfusion killed 700 more and the serum 24 hours after 900 more staphylococci per c.cm. than before.

Example 7.—Demonstration by the implanting and explanting method of increased hæmo-bactericidal power obtained by immuno-transfusion of 500 c.cm. of blood from a donor who had half an hour before been inoculated intravenously with 170,000 streptococci.

Patient with puerperal streptococcic septicæmia.

Number of staphylococci implanted per 5 c.mm. of blood.	Number of colonies which developed on agar when 5 c.mm. of blood drawn before immuno-transfusion was explanted.		Number of colonies which developed on agar when 5 c.mm. of blood drawn immediately after immuno-transfusion was explanted.	
	Immediately.	After ½ hour.	Immediately.	After ½ hour.
55	32	94	38	48
29	10	53	15	11
10	6	16	10	7
7	5	6	8	1
4½	3	2	5	2
105	56	171	76	69

We have here the results of two separate assays. When assayed by implanting and explanting immediately (the comparison is here between columns 1, 2, and 4), the blood drawn off immediately after immuno-transfusion showed a decline rather than an improvement. When assayed by implanting and explanting after half an hour (the comparison is here between columns 1, 3, and 5), the blood drawn off immediately after immuno-transfusion shows great improvement. While in the blood drawn off before immuno-transfusion 105 microbes had increased to 171, and in the blood, drawn off after, the 105 had decreased to 76.

I may just advert to one further point of theoretical interest in connexion with immuno-transfusion. This is that when the donor, or his blood, has been inoculated with too large a quantum of vaccine, or where insufficient time has intervened between inoculation and transfusion, instead of a positive, a negative phase, such as that which would have been produced by a direct inoculation of vaccine, will supervene.

I may now pass from the illustration of the effects of immuno-transfusion to illustrate those of the direct inoculation of vaccines into patients whose blood has after examination by the chiastic or vaccine-response test, or on general clinical grounds, been adjudged to be capable of making immunising response. It will—for we are here dealing with blood conditions which are, of course, fundamentally the same as those obtaining in health—suffice here to adduce a couple of examples.

Example 8.—Increased hæmo-bactericidal and sero-bactericidal power obtained by the intravenous inoculation of 700,000 dead streptococci (160 per c.cm. of patient's blood).

Surgical nurse suffering from an acute streptococcus infection originating in a punctured wound of the finger. Temperature 105° F. Measurement of hæmo-bactericidal power by implanting staphylococcus by the wash and after-wash procedure into a sequence of 10 c.mm. volumes of blood in a long capillary tube.

—	Number of colonies which developed in volumes—					Total in—	
	1	2	3	4	5	40 c.mm.	1 c.cm.
10 P.M.: Blood immediately before the intravenous inoculation	+	6	5	2	2	21·5	540
	+	16	8	4	0		
Blood 3 mins. after the inoculation	+	6	0	0	0	7	175
	+	6	2	0	0		

The sign + indicates that the colonies were too numerous for accurate enumeration.

Sero-Bactericidal Power (same technique).

—	Number of colonies which developed in volumes—					Total in—	
	1	2	3	4	5	40 c.mm.	1 c.cm.
3 P.M.: Serum from blood drawn 7 hours before intravenous inoculation	+	20	12	5	1	37	1000
	+	17	14	3	1		
	+	19	12	5	2		
10 P.M.: Serum from blood drawn immediately after inoculation	+	12	9	0	0	22·5	550
	+	17	4	3	0		
12.30 A.M.: Serum from blood drawn 2½ hours after inoculation ..	+	10	5	2	0	14·5	360
	+	9	2	1	0		

The patient's temperature by next morning had come down from 105° to 99°, and she was quite out of danger. The finger afterwards began to suppurate and was incised, and the patient made a rapid recovery.

Example 9.—Increased hæmo-bactericidal power obtained by intravenous inoculation of 30,000 streptococci.

Patient suffering from streptococcal septicæmia and endocarditis. Slide-cell inculturing method.

Number of staphylococci implanted.	Number of colonies which developed in blood drawn off—	
	Before intravenous inoculation.	20 mins. after intravenous inoculation.
160	31	12
80	16	9
40	7	7
20	3	3
10	4	0
5	0	0
315	61	31

Example 10.—Increased sero-bactericidal power obtained by intravenous inoculation of 125,000 dead staphylococci (50 per c.cm. of patient's blood).

Patient with streptococcal endocarditis (M.F.). June 19th, 1922, sera from bloods drawn off before and at intervals after inoculation. Measurement of sero-bactericidal power by implantation of 2·5 c.mm. of staphylococcus suspension into 50 c.mm. samples of serum.

	Average of samples tested.	Colonies.
Serum before inoculation	6	67·5
,, ½ hour after inoculation ..	3	41·5
,, 2 hours ,, ,, ..	3	49·5

Calculation shows that here the serum half an hour after inoculation killed 520 more, and two hours after inoculation 360 more staphylococci than before.

Example 11.—Increased sero-bactericidal power obtained by intravenous inoculation of 130,000 dead streptococci (55 per c.cm. of patient's blood).

Same patient (Example 10) with streptococcal endocarditis (M.F.). Procedure as before (Example 10).

Two volumes of serum *immediately before inoculation* furnished 82 and 91 colonies, average 86·5.

Two volumes of serum *half an hour after inoculation* furnished 82 and 99 colonies, average 90·5.

Two volumes of serum *two hours after inoculation* furnished 78 and 88 colonies, average 83.

One volume of serum *four hours after inoculation* furnished 32 colonies.

Calculation shows that the serum four hours after inoculation killed 1090 more staphylococci per c.cm. than before.

Example 12.—Increased hæmo-bactericidal power to staphylococcus obtained by the inoculation of 200,000 typhoid bacilli 80 per c.cm. of patient's blood).

The same patient (Examples 10 and 11) with streptococcal septicæmia and endocarditis (M.F.). Measurement of hæmo-bactericidal power by implantation of 2·5 c.mm. of progressive dilutions of staphylococcus culture into 50 c.mm. samples of blood and inculturing these in slide cells.

—	Number of colonies of staphylococcus which developed in volumes—								
	1	2	3	4	5	6	7	8	Total.
Blood drawn immediately before inoculation	32	16	9	4	5	1	0	0	67
Blood after inoculation..	23	7	3	1	0	1	1	1	37

The number of staphylococci implanted was the same for the two bloods.

Example 13.—Increased hæmo-bactericidal power obtained by the intravenous inoculation of 40,000,000 staphylococci (8000 per c.cm. of patient's blood).

Patient with chronic hectic temperature following upon staphylococcal infection of the breasts (M.F.). Procedure as above (Example 12).

—	Number of colonies of staphylococci which developed in volumes—								
	1	2	3	4	5	6	7	8	Total.
Blood drawn immediately before inoculation	31	13	7	3	2	0	1	1	58
Blood one hour after inoculation	6	2	1	1	0	0	0	0	10

The number of staphylococci implanted was the same for the two bloods.

CONCLUSION.

I have now finished with the setting out of the data of individual experiments, and would, in conclusion, set out two considerations of a more general order. The first has reference to the question of the therapeutic prospects here opened up. The experiments which have been set out have brought into prominence the fact that in immunisation quantitative considerations dominate the situation. When we want to evoke immunising response in the blood we must employ one particular range of doses. And when we want to ascertain what has been achieved we must again employ one particular range of doses. Once that principle has been accepted, and we realise that in each case only a definite measure of additional anti-bacterial power is engendered, and that with it only such and such an additional number of microbes can be killed, it becomes possible to get down to figures.

In the experiments incorporated in this paper the increased anti-bacterial power engendered runs, as calculation shows, generally into the killing of several additional hundreds or exceptionally several additional thousands of staphylococci per c.cm. It never gives us an additional killing of tens or hundreds of thousands. These figures, then, give us our upper and lower limits. Within that range there is, as reflection will show, much useful therapeutic work to be accomplished. But we must not close our eyes to the fact that, just as there is an assaying dose of living microbes which no immunised blood can contend against, so there must be a very definite limit to the volume of infection which intravenous inoculation of vaccines, or immuno-transfusion can cope with. And in computing that volume of infection we must take into reckoning not only the microbes actually circulating in the blood (those even in very severe cases of streptococcal septicæmia do not amount to more than a very few hundreds of microbes per c.cm.), but the total bacterial population in the internal organs, which may run into indefinite millions.

The second point—which comes in appropriately at the end of this paper, which began by showing how always a new code of principles comes and supersedes or modifies its predecessor—is that it behoves us to realise that in every code of principles there are tenets based only upon inference as well as tenets based upon direct experiment. But while we regard that, we should also keep before us that in every succeeding code those elements which rest on inference grow less and less, and those which rest directly upon fact—those which are established by laboratory methods—grow more and more. So that in the end, in every science, enduring principles will be reached.

In conclusion, I would express to the Medical Research Council grateful acknowledgments for those external circumstances which allow of the undertaking of protracted and undisturbed researches, and for the valuable aid of Dr. Leonard Colebrook.

ARTIFICIAL PNEUMOTHORAX:

ITS APPLICATION TO CASES OTHER THAN THOSE OF PULMONARY TUBERCULOSIS.

By J. J. PERKINS, M.B., B.C. Camb., F.R.C.P. Lond.,

AND

L. S. T. BURRELL, M.D. Camb., M.R.C.P. Lond.,

PHYSICIANS TO THE BROMPTON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.

The cases described in this paper illustrate the application of artificial pneumothorax to conditions of thoracic disease other than pulmonary tuberculosis. They form a consecutive series of 21 cases taken as admitted to our wards and show the results of the treatment whether successful or not. Two cases only have been omitted, both of bronchiectasis, in which artificial pneumothorax was tried, but was found to be impossible owing to the presence of widespread adhesions. The series includes seven cases of abscess of lung, six of bronchiectasis, three of recurrent profuse hæmoptysis, two of chronic pleural effusion, and three of effusion complicating growth. It is not suggested that none of these cases were tuberculous, though the great majority certainly were not. The three cases of recurrent hæmoptysis and the two of chronic effusion may possibly have originated in tuberculosis, but as no tubercle bacilli were ever found they are not claimed here as such, and treatment was undertaken for relief of the immediate condition.

Abscess of Lung.

The following cases were of abscess of the lung:—

Case 1.—Female aged 34. Cough began in August, 1919, after confinement; there was sputum, which increased in quantity and became offensive. Hæmoptysis (6 oz.) in June and again in August, 1920, at which time the daily quantity of sputum was 4 oz. and the weight 120 lb. There were signs of excavation at the base of the left lung. Artificial pneumothorax was induced on Sept. 30th. In March, 1921, her weight was 146 lb. and there was about an ounce of sputum daily, but it was not then offensive. In November her weight was 173 lb. and there was no sputum. Treatment was then stopped and she has remained well and free from symptoms.

CASE 2.—Female aged 26. An abscess developed in the base of the right lung after confinement in August, 1920. In June, 1921, she had 7 oz. of sputum daily, and her weight was 106 lb. Artificial pneumothorax was induced, and she gradually improved, but the symptoms recurred whenever the lung was allowed to re-expand. In August, 1922, treatment was stopped and the lung has been re-expanding since without any return of the symptoms. Her weight is now 124 lb. and she has had no sputum since April, 1922.

CASE 3.—Male aged 30. Pneumonia in January, 1920. Cough and much sputum since. Condition gradually became worse in spite of vaccine and other treatment. In July he was toxic, had evening temperatures of 102° F. and much offensive sputum. There were signs of an abscess at the base of the right lung. Artificial pneumothorax was then induced, and the lung kept collapsed until December, 1920, when it was allowed to re-expand. He had then lost all sputum and improved in his general health. The symptoms have not recurred and he remains well.

CASE 4.—Male aged 40. An abscess at the base of the right lung followed an operation for nasal polypi in May, 1921. In October he had a large amount of very offensive sputum. His temperature ranged between 101° and 102·6° F.; he was toxic and acutely ill. Pneumothorax was induced, but four days later the abscess broke into the pneumothorax cavity. A large amount of fœtid pus was aspirated, and the pleural cavity was washed out every day until clear. Ten days later he was very much better; the pleural cavity was then drained and he made an uninterrupted and complete recovery.

CASE 5.—Male aged 50. Left pleurisy in January, 1921, followed by cough, offensive sputum, and two attacks of hæmoptysis. Signs of abscess of lung found in left axilla. In July, 1921, a pneumothorax was induced, and he improved quickly, leaving hospital in October. A few days later, whilst running for an omnibus, he felt a sharp pain, and the abscess ruptured into the pneumothorax cavity. Pus was aspirated, and the pleural cavity washed out until clear and later drained. He made a good recovery and is now free from all symptoms.

CASE 6.—Male aged 42. An abscess developed in the base of the right lung after appendicectomy in December, 1921. In February, 1922, there were 10 oz. of offensive sputum daily, and the patient was very ill. Pneumothorax was induced, the general condition improved, and the amount of sputum was slightly reduced, but it remained offensive. X ray showed a large patch of adherent pleura at the back, preventing full collapse of the lung. In June a partial thoracoplasty was performed by Mr. W. H. C. Romanis, portions of three ribs being removed from the right base. The immediate improvement in the patient was remarkable. He lost all cough and sputum, and his general condition became normal in a few weeks. There is only a small scar and no deformity. He has gained a stone in weight.

In this case a small amount of fluid formed in the pneumothorax cavity during treatment, but it was a very small amount and soon disappeared. It is remarkable as being the only one of our non-tuberculous cases in which an effusion formed.

CASE 7.—Male aged 36. A right-sided artificial pneumothorax was induced for abscess of lung. The sputum was reduced from 7 to 2 oz. a day, but remained at that. X ray showed a large adhesion at the back preventing full collapse of lung. An operation was performed and the adhesion divided, but the patient died the next day.

Bronchiectasis.

The following were cases of bronchiectasis:—

CASE 8.—Female aged 23. Bronchiectasis of lower lobe of right lung following pneumonia in 1915. Pneumothorax induced at the end of 1918, with immediate improvement, the sputum disappearing. When the lung was allowed to re-expand the symptoms returned; the lung was therefore kept collapsed until after two years, when the pneumothorax cavity was beginning to close owing to contraction of adherent pleura. The treatment was stopped in March, 1921. She has now no sputum and has remained quite well, except for a little dry cough.

CASE 9.—Female aged 22. Cough and sputum since an operation for removal of the tonsils and adenoids in 1910. Worse since influenza in 1919. Had had several attacks of hæmoptysis, and was coughing up about 3 oz. of very offensive sputum daily in July, 1921. Signs of bronchiectasis at left base, and to a very slight extent at right base. Left lung collapsed in July, 1921; sputum promptly reduced to about an ounce a day, but remained offensive. In January, 1922, the lung was allowed to re-expand and the amount of sputum did not increase. In February the right lung was collapsed, but as no further reduction in the quantity of sputum occurred, it was allowed to re-expand at the end of March. Patient's weight constant throughout the treatment, and her condition is much the same as before pneumothorax was induced, except that she has less sputum.

CASE 10.—Male aged 15. Cough with increasing quantity of sputum since influenza in July, 1920. In April, 1922, he had 15 oz. of offensive sputum a day, was toxic, wasted, and had signs of excavation at base of right lung. Pneumothorax induced on April 22nd; by May 12th general condition very much improved, and daily amount of sputum reduced to 3 oz. Still under treatment, amount of sputum varying from ½ oz. to 3 oz. a day.

CASE 11.—Male aged 36. Cough has continued since influenza in 1920. Clubbing of fingers developed with dyspnœa, and about 4 oz. of offensive sputum a day, and signs of bronchiectasis at the left base. A left pneumothorax induced in January, 1921, and is still being kept up. Sputum now about 2 oz. a day and no longer offensive. When the lung is allowed to re-expand the amount of sputum increases. General condition improved.

CASE 12.—Male aged 41. Cough since left pleurisy in August, 1917. In October, 1920, toxic, had evening temperatures of 100° F., from 6 to 10 oz. of offensive sputum daily, and had been confined to bed for two months. Signs of bronchiectasis at left base. Pneumothorax was induced and he immediately improved. By March, 1921, he had gained 10 lb. in weight and had very little sputum. The collapse, however, was not complete, for there were several separate adhesions as well as some adherent pleura, by the contraction of which the lung was gradually drawn out, the pneumothorax cavity becoming smaller and smaller. He kept well, however, until December, when the symptoms began to return. In June, 1922, he was again coughing up about 7 oz. of sputum daily and thoracoplasty was performed. His symptoms improved, and he seemed to be doing extremely well, but developed pneumonia and died some three weeks after the operation.

CASE 13.—Female aged 33. A right artificial pneumothorax induced for long-standing bronchiectasis. Eight months later the amount of sputum much less, the general condition improved, and she had gained over a stone in weight. Owing to adhesions, however, only partial collapse was possible and thoracoplasty was performed. The wound became infected and she died of sepsis.

In two other cases, as we have mentioned, artificial pneumothorax was attempted but found to be impossible owing to pleural adhesions.

Hæmoptysis of Unknown Origin.

The following cases were of hæmoptysis, of which the origin was unknown.

CASE 14.—Male aged 28. Hæmoptysis of 4 oz. in 1906. Similar attacks about once a year until 1918, since when they have become more frequent. Three hæmoptyses in May, 1920, and afterwards about one a month—the largest 10 oz. A few râles and dullness at right base. A right artificial pneumothorax induced during an attack of hæmoptysis in March, 1921; lung kept collapsed until July, 1922, since when it has been allowed to re-expand. No hæmoptysis since March, 1921.

CASE 15.—Female aged 27. In November, 1919, patient coughed up half a pint of blood. No tubercle bacilli found in sputum, and she kept well until August, 1920, when she had another large hæmoptysis. After this there were other attacks, the last being in September, 1921, when she had hæmoptysis—a quart. On examination, signs of infiltration at left apex and in axilla; X rays showed a dense opacity at left apex. Pneumothorax induced in November, 1921; since then no further hæmoptysis. No cough or sputum; patient is keeping fit and has returned to work. The pneumothorax is being kept up.

CASE 16.—Female aged 32. Hæmoptysis in 1914; since then has had an attack, about a cupful, every two or three months. Her general condition remained good. In June, 1920, an area of dullness and bronchial breathing were found at the right base and X ray examination showed a dense opacity in this region. A right pneumothorax was induced and the lung well collapsed. In spite of this she had another attack of hæmoptysis in September, and again in January, 1921, after which the treatment was stopped. Her general condition has kept good, but she still has periodical attacks of hæmoptysis.

Chronic Pleural Effusion.

The following cases were of chronic pleural effusion.

Case 17.—Male aged 44. Left pleural effusion in January, 1920. It had been aspirated four times, but the fluid quickly reaccumulated, and in August, 1920, the left pleural cavity was full. The fluid was then removed and replaced with oxygen. This was repeated in September and October, 1920. After this the fluid did not re-form, and the lung very quickly re-expanded. He has since kept fit and at work.

Case 18.—Female aged 30. Right pleural effusion following pneumonia in 1919. This had been aspirated five times by March, 1920, when there was a large right pleural effusion: 1800 c.cm. were removed and replaced with 1200 c.cm. of oxygen. The liquid contained cholesterin crystals, but was sterile, and no tubercle bacilli were found. In April 1100 c.cm. of liquid were removed and replaced with 800 c.cm. of oxygen. In May X ray showed the lung re-expanding and only a small amount of liquid in the pleural cavity. In July, 1920, there was no effusion and the lung had re-expanded. In the remaining three cases (19, 20, and 21) growth of mediastinum or pleura was present, and replacement failed to prevent the reaccumulation of the pleural effusion.

Conclusions.

It will be seen from these cases that artificial pneumothorax may be of value in abscess of lung, bronchiectasis, hæmoptysis of unknown origin, and recurrent pleural effusion. In abscess of lung the success of artificial pneumothorax evidently depends on the presence or absence of adhesions. Where these are absent artificial pneumothorax is sufficient to effect a cure and render a severer operation unnecessary. Considering the uncertainty of discovering the abscess cavity it is certainly to be preferred to drainage. When the abscess is superficial the presence of adhesions may lead under pneumothorax to its intrapleural rupture (Cases 4 and 5) necessitating drainage of the pleura. If the adhesions are widespread they may stand in the way of complete collapse (Case 6) and prevent success, necessitating thoracoplasty. But even so, we advocate artificial pneumothorax as routine procedure on the ground that it may be sufficient in itself and, where not, that the symptoms are relieved and the general condition of the patient improved, enabling him better to face the severer operation.

Success in bronchiectasis, as in abscess of the lung, depends on adhesions which in Cases 12 and 13 led to disappointing results, and in two cases rendered the induction of pneumothorax impossible. Case 8, however, shows that artificial pneumothorax may be completely successful when prolonged (two years), and the failure in Case 9 we may attribute to insufficient length of treatment. This view is upheld by Cases 10 and 11 in which the treatment is still being continued with results already beneficial and hopeful. In the cases of recurrent hæmoptysis and chronic effusion success was striking.

A FATAL CASE OF PRE-RENAL TOXÆMIA

SHOWING CLINICAL SIGNS OF CHRONIC PARENCHYMATOUS NEPHRITIS.[1]

By W. N. Goldschmidt, B.Ch. Camb., M.R.C.P. Lond.,
LATE HOUSE PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL, LONDON.

This case is of interest from the point of view of the relationship between the symptoms and signs of "parenchymatous nephritis," and the condition actually found in the kidney, both during the disease and post mortem. The effect of decapsulation and other remedies is also discussed.

History.—On Jan. 28th, 1922, a man, aged 42, was admitted to hospital complaining of swelling of his legs for seven weeks, and of his "stomach" and back for six weeks. Additional symptoms were very troublesome—viz., flatulence, shortness of breath on exertion, and occasional headaches. The only serious illness from which he had suffered was a febrile attack ("influenza") in Egypt in 1918. There was no venereal history.

Condition on Examination.—Great pallor and marked œdema of legs, abdomen, and back, and also ascites. Cardio-vascular system showed no abnormalities, though the heart sounds were very faintly heard. Systolic blood pressure, 132 mm. Respiratory system: evidence of some pleural effusion at both bases, especially the right. Tongue was furred, tonsils rather injected, and gums showed pyorrhœa. Abdomen was distended by fluid, and also by meteorism, especially in upper part. Patient complained of a dull pain all over abdomen, and great flatulence after meals. Urine: About 200 c.cm. passed in 24 hours, sp. gr. 1030, brown colour, acid, containing about 2 per cent. of albumin; microscopic examination showed red blood-cells and numerous granular, hyaline, and epithelial casts; the urea-concentration by MacLean's test was nearly normal, averaging 1·7 per cent. Blood-urea was within normal limits (33 mg. per 100 c.cm.). Wassermann reaction negative. Fundi, examined ten days after admission, normal.

Treatment.—At first consisted of rest in bed, salt-free diet, and a diuretic mixture containing potass. acetat., tr. scillæ, sp. æther. nit., and succ. scoparii. In four days quantity of urine passed in 24 hours rose to 660 c.cm. On sixth day hot-air baths once daily were used, but no satisfactory perspiration was produced. Bowels were very obstinate, and large doses of jalap, given with hot water, were required to achieve any result. From tenth day urea (1 dr.) was given four times a day for a few days, with no effect on diuresis, and then diuretin (gr. 20), t.d.s., with no result; the urine continued to average about 500 c.cm. daily. Patient was drinking fairly freely, but little fluid was excreted, either by skin or by bowels. The flatulence was very troublesome, and had to be relieved by hot applications and carminatives. No progress being made by medicinal and dietetic means, and the history being comparatively short, it was decided to try decapsulation of a kidney.

First Operation.—Three weeks after admission his right kidney was decapsulated by Mr. Gwynne Williams, one kidney only (the right) was operated on to begin with, in order to watch the result. The kidney was of normal size and colour; a slit was made in the capsule (which was not tense), and a small piece of kidney substance removed for examination; the capsule was then separated from the kidney all round. The peritoneal cavity was opened and two to three pints of ascitic fluid allowed to escape; this was milky and opalescent from the presence of lecithin-globulin (Dr. Mackenzie Wallis). Intestines pale, but no visible peritonitis.

Course of Condition.—Four days later the urine had risen to 900 c.cm., and the œdema was rather less; ten days after the operation it rose suddenly to 1200 c.cm. (albumin 0·36 per cent.), but within four days it dropped again as quickly to 600 c.cm. Urea was now again tried and pushed in doses of 15 g. t.d.s., except when the patient was sick; the urine now increased within 18 days to 1600 c.cm. in 24 hours and then averaged 1200 c.cm. for about 12 days. The general condition of the patient was, however, but little altered and the œdema not materially diminished. The abdomen and scrotum were again tense.

Second Operation.—With the idea that the increased urinary output might have been due partly to the operation, it was decided to decapsulate the left kidney. Accordingly, on April 5th, 1922, seven weeks after the first operation, a second operation was performed by Mr. Gwynne Williams. The left kidney and its capsule were normal in appearance and in size; the capsule (which was not tense) was slit and retracted; the peritoneal cavity was opened and several pints of milky fluid like that at the first operation were removed. The intestines were pale but otherwise normal. For the next two days the quantity of urine dropped to 700 c.cm., albumin still being present. On the third day the urine rose again to 1350 c.cm., but after that it steadily decreased in amount and the œdema re-accumulated. Three weeks after the operation an attempt was made to reduce the œdema by giving him less to drink (only about 1½ pints daily), salt-free diet, purgatives, and theocin sod. acet. gr. 4, tr. digitalis ♏ 7½, and sod. sulph. gr. 15 t.d.s.; the increasing oliguria could not be stayed.

---

[1] Read at the combined meeting of the Sections of Medicine and Ophthalmology of the Royal Society of Medicine on Dec. 8th, 1922.

Fatal Termination.—On April 27th the blood-urea had risen to 48 mg. in 100 c.cm. Abdomen was now very distended again and vomiting started. On May 9th, everything else having failed to relieve the œdema, Southey's tubes were inserted into his feet with scrupulous aseptic precautions. A very large quantity of fluid was drained off (four pints on the first day). The abdominal distension, which was partly gaseous, was not relieved. The chlorides in the urine were markedly diminished. After a few days the feet became red and painful; the temperature dropped to 96°; the blood pressure, 132 mm. Hg on admission, soon falling to 120 mm., where it remained, now fell to 90 mm., and the patient became drowsy and sometimes semi-comatose. On May 30th his blood-urea had risen to 63 mg. in 100 c.cm. The albumin in his urine on June 1st was 0·5 per cent., on the 2nd 1·25 per cent., and on the 3rd 2·5 per cent. He was now somnolent, often sick, and there was evidence of cellulitis in the legs. On June 5th he died.

Autopsy.—Externally a few petechiæ were seen on the arms. Incisions into the dorsa of the feet showed the cellular tissue to be distended with pus. Heart small, only 5½ oz. in weight, and atrophic; a few patches of atheroma seen in aorta and coronary arteries; heart muscle dark brown. Lungs, &c.: Each pleural sac contained about 6 oz. clear fluid; scattered fibrous adhesions on both sides; lungs congested and œdematous. Peritoneum: A large quantity of turbid ascitic fluid; considerable flakes of fibrinous exudate found on peritoneal surface. Intestines: Sigmoid colon contracted, apparently by thickening of bowel walls; mucous membrane showed slaty grey patches, and was œdematous and congested; no ulceration or evident scarring; affected area sharply marked off from the contiguous normal gut. Kidneys: Left kidney, normal in size, removed and injected with preservative fluid soon after death; right kidney, of normal size and weighing 5 oz., not injected with preservative fluid; surface smooth and rather pale; cortex, medulla, and vessels normal.

Microscopic Sections of Kidneys.—Mr. T. W. P. Lawrence described the sections as follows:—

1. *Section of right kidney, piece removed at first decapsulation operation.*—(*a*) Localised cloudy swelling and necrosis of tubules, probably acute; adjacent areas quite normal. (*b*) Some slight chronic changes shown by thickening of capsules. (*c*) Proliferation of epithelium of glomerular tufts. (*d*) Slight increase of interstitial tissue between tubules in places. (*e*) Small localised effusions of red corpuscles.

2. *Section of right kidney, piece removed post mortem, the organ not having been injected with preservative fluid.*—(*a*) All acute changes above described absent. (*b*) chronic changes shown by thickening of capsule, only slight, as above. (*c*) Numbers of nuclei in glomerular tufts fairly normal. Corpuscles not so large as in above section. (*d*) Slight interstitial changes between tubules, as in above section. (*e*) No effusion of red corpuscles. (Considerable autolytic change in tubular epithelium.)

3. *Section of left kidney, piece removed post mortem, the organ having been injected with preservative fluid very soon after death.*—Microscopic details of this kidney identical with those met with in right kidney, no acute cloudy swelling or necroses being visible in tubular epithelium. Autolytic changes minimal.

Summary.—"The sections of the piece of kidney removed during life show slight but definite changes such as could be produced by some toxic agent arriving by the blood-stream. The sections of the pieces removed after death only show the slight chronic changes met with in the sections of the piece removed during life and are very little different in appearance from those of a normal kidney."

Remarks.

This man died from an illness the symptoms of which were typically those which have been attributed to "chronic parenchymatous nephritis"; but his kidneys were found at the post-mortem examination to be normal macroscopically, and practically normal microscopically. His actual death was, perhaps, due to or hastened by the infection which followed insertion of Southey's tubes, but before the latter were reluctantly resorted to he was steadily progressing to the inevitable end. The section from the piece of right kidney taken during life at the first decapsulation operation showed some parenchymatous changes of an apparently acute nature. As the right kidney showed none of these appearances post mortem, decapsulation may have restored the kidney, but did not improve the pre-renal toxæmia.

I am forced to the conclusion (unless in such cases one thrusts aside as valueless *all* microscopical evidence of the presence or absence of disease) that this long, insidious, and fatal illness was not accounted for primarily by the state of the kidneys. The heart was very small and in a condition of brown atrophy—always looked upon as a secondary phenomenon, not as a primary morbus cordis "sui generis"—but the heart actually showed considerably more evidence of disease than the kidneys. Even supposing the kidneys *had* shown parenchymatous changes post mortem, there would be no more reason for considering the kidney degeneration primary than that of the heart. Incidentally, there were no signs of renal inefficiency during the earlier and greater part of the illness, except oliguria (which occurs in heart disease), albuminuria (which occurs in 6 per cent. of healthy adults), and diminished excretion of chlorides (which occurs also in fevers, especially pneumonia, and is not incontestably the result of damaged kidneys). Furthermore, the œdema is not easy to explain as due entirely to the retention of chlorides, since œdema is not a feature of pneumonia, and does not even occur in obstructive suppression of urine or after removal of the only kidney. It is of great importance to note that, although towards the end of his illness the kidneys were only slightly, or possibly not at all, damaged, the blood-urea rose, so that an abnormally large amount of urea may be present in the blood with slight or no changes in the kidneys. It would, therefore, seem as if this man's illness were due to some pre-renal poison which caused exudation into the tissues, and incidentally damaged some of the tubules of the right kidney; but the latter had recovered by the time the man died.

I wish to thank Dr. Batty Shaw and Mr. Gwynne Williams for the use of their case reports, and Mr. T. W. P. Lawrence for his description of the microscopical sections.

THE SOFIE A. NORDHOFF-JUNG CANCER RESEARCH PRIZE.—Dr. Sofie A. Nordhoff-Jung, of Washington, Columbia, U.S.A., has founded an annual prize of $500 bearing the above title. This prize is designed to encourage researches in the ætiology, prevention, and treatment of cancer. It will be awarded by a commission composed of members of the University of Munich, Bavaria, and be granted for the first time in December, 1923. The commission consists of Professors Borst, Doederlein, and Sauerbruch, with Prof. von Romberg as chairman. This body is empowered to elect successors. The award will be made as a recognition of the most conspicuous work in the world literature bearing on cancer research, done at a time antecedent to the allotment of the award. Though the prize will not be awarded on a competitive basis the commission invites all research workers in cancer to submit literature on this subject.

OBSERVATIONS ON THE EFFECT OF HISTAMINE ON THE HUMAN GASTRIC SECRETION.

BY ALISTER R. MATHESON, M.B., M.R.C.P. EDIN.,
TUTOR IN CLINICAL MEDICINE, ROYAL INFIRMARY, EDINBURGH;

AND

SYDNEY E. AMMON, M.B., CH.B. EDIN.,
CLINICAL ASSISTANT, ROYAL INFIRMARY, EDINBURGH.

(From the Department of Therapeutics, Edinburgh University.)

THE object of this paper is to give an account of an investigation into the effect of histamine (β-iminazolylethylamine) in small doses on the human gastric secretion. Several other workers have studied the effect of this substance on the gastric secretion of animals; Popielski,[9] Keeton, Koch, and Luckhardt,[6] Rothlin and Gundlach,[10] and Lim[8] found that histamine has a marked effect in stimulating gastric secretion in dogs and cats. Rothlin and Gundlach consider that, in its mode of action on the motor and secretory functions of the stomach, it behaves as a parasympathomimetic substance; they have suggested its employment for diagnostic and therapeutic purposes. On the other hand, Koskowski[7] denies that histamine acts on the vagal terminations; he believes, with Popielski, that it acts directly on the secretory cells. The effect of histamine on human gastric secretion has been studied so far as we are aware only by Carnot, Koskowski, and Libert.[2] These observers carried out their investigations by means of the Einhorn tube. They injected the drug subcutaneously and withdrew the gastric juice at intervals. The doses employed by them were 0·75–1·75 mg., the preparation used was the histamine ("crystallisée") of Hoffman Laroche. They describe an increased flow of gastric juice 30 to 55 minutes after injection, accompanied by an augmentation of total acidity, free HCl, and proteolytic activity.

Technique.

Our observations were carried out on 12 hospital patients, most of whom were convalescent and without any obvious disturbance of gastric function. The "one hour" test-meal was employed for purposes of comparing the nature of the gastric response to a constant test-meal (tea and toast) with the histamine response. The patients received no food for at least 12 hours previous to the experiment. The first thing in the morning a Rehfuss tube was passed into the stomach and the "overnight" juice withdrawn by means of a Record syringe, the position of the patient being changed during withdrawal in order to ensure complete emptying of the stomach. Ten minutes later aspiration of the entire stomach contents was again performed and again in another ten minutes, in order to determine the rate and nature of the "resting" secretion—i.e., the secretion occurring in the interval between the withdrawal of the "overnight" juice and the subsequent injection of histamine. Five minutes later a dose of histamine was injected subcutaneously, and following this the stomach contents were completely aspirated at intervals commencing five minutes after the injection and thereafter every ten minutes until secretion had ceased or returned to the normal.

The preparation of histamine employed was the ergamine acid phosphate of Messrs. Burroughs Wellcome and Co., containing approximately one-third of histamine base.[3] It was dissolved in water and made up so that 1 c.cm. of the solution contained 1·5 mg. of the salt; to guard against deterioration only small quantities were prepared at a time and these divided into doses and sealed in ampoules. The solution (0·9–1 c.cm.) was administered to the patient by subcutaneous injection in the upper arm. Any possibility of the psychic stimulation of gastric secretion by sight or smell of food, &c., was carefully avoided, and the disturbance caused to the patient by the Rehfuss tube reduced to a minimum by careful manipulation. The specimens of gastric content obtained were measured and examined for total acidity, free HCl, pepsin, mucus, and bile. Total acidity and free HCl were estimated by titration with N/50 sodium hydroxide, using as indicators dimethylaminoazobenzene and phenolphthalein, the results being stated in terms of the number of c.cm. of N/10 NaOH required to neutralise 100 c.cm. of gastric contents; the juice was not filtered when employed for titration. Pepsin was estimated by the method of Mett as modified by Nirenstein and Schiff. The Mett tubes were prepared by the Christiansen method,[5] and the results given in millimetres of egg-white digested. Mucus and bile were noted by naked-eye examination only. Pulse- and respiration-rates were counted at frequent intervals (10 minutes) throughout the investigations and the blood pressure estimated by the Tycos sphygmomanometer.

The following tables and charts represent the results from three of our cases, which are typical of the remainder in the series.

Results.

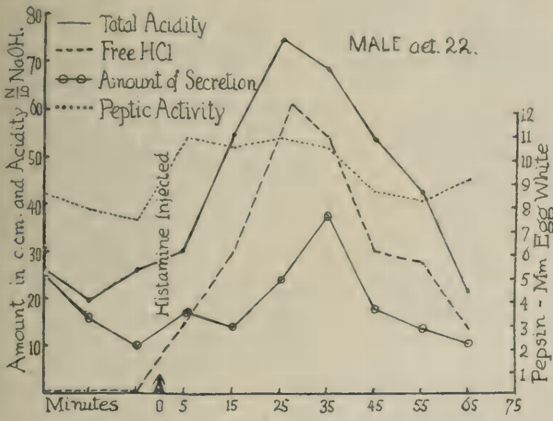
The general similarity of the response to histamine on the part of different individuals is well shown in the tables and charts. The amount of juice secreted in a given time, the total acidity, and free HCl figures all show an increase after histamine. This increase becomes evident within 15 minutes of the injection and continues until a maximum is reached. Maximum acidity is attained about half an hour after injection, while the maximum amount of secretion is not registered until some minutes later. The decline from the maximum point is usually more gradual than the rise, and occurs progressively until the normal is obtained. The curves for total acidity and free HCl are remarkably parallel in their course. The maximum acidity attained varies in individual cases, and we have observed maximum total acidity figures in normal individuals ranging from 75 to 125.

FIG. 1.



0	0	0	0	0	0	0	0	0	0	BILE
+++	+++	++	+++	+++	+0	+0	+	+	+	MUCUS

Both here and in Fig. 2 the abscissæ represent time in minutes, the arrow indicating the moment of injecting histamine. The left ordinate represents both amount of secretion in c.cm. and also acidity (total and free HCl) in terms of c.cm. N/10 NaOH. The right ordinate represents mm. of egg-white digested in the Mett tubes. The absence or presence of mucus and bile are indicated below the chart (+0 = trace).

It will be noted that the curve of peptic activity follows in general the secretion and acidity curves. In some cases, however, the pepsin curve is less regular; nevertheless, it is of interest that in every one of our cases peptic activity registered its maximum in a shorter time than either acidity or rate of secretion. As regards mucus, it has been noted that this is usually plentiful in the juice obtained before the injection of histamine. Soon after injection, however, it diminishes not only relatively, but absolutely in amount, and this decrease appears to bear a relationship to increased acidity. It may be that the absence of the neutralising effect of the mucus is one factor contributing to the great rise in acidity. Without attempting to discuss its bearing on Boldyreff's theory[1] of the automatic regulation of gastric acidity by the regurgitation of alkaline fluids through the pylorus, we have observed that while in many of our cases the acidity of the gastric contents reached very much higher levels than those following a test-meal, bile was noted only infrequently. These contents, of course, were only permitted to remain in the stomach for short intervals before being withdrawn.

The pulse-rate and arterial blood pressure in our cases have sometimes shown an increase after the histamine injection, but these effects we attribute to the excitement of the patient. Flushing of the face was noted to occur shortly after the injection; this is in accordance with the observations of Dale and Richards[4] on the vaso-dilator action of histamine. No alterations of the respiratory-rate were noted in any of the cases. No patient complained of any discomfort or pain whatsoever either general or referable to the stomach throughout the investigation.

Summary.

1. Histamine in small doses given subcutaneously excites a flow of gastric juice in man.

2. The peptic activity increases after the injection and reaches its maximum, usually in about 5–15 minutes. Both total and free HCl increase and attain their maxima shortly after the pepsin maximum is registered. The secretory-rate follows a similar course, and usually attains its maximum last of all.

3. The dose employed by us to evoke gastric secretion does not produce any harmful gastric or general disturbance. This being the case, it seems possible that histamine may be employed as a means of investigating the state of gastric secretory function and perhaps as a therapeutic agent.

A FATAL CASE OF ACUTE INTESTINAL OBSTRUCTION

RESULTING FROM TRAUMATIC DIAPHRAGMATIC HERNIA.

By B. HOLROYD SLATER, F.R.C.S. Eng.,
SURGEON TO ST. LUKE'S HOSPITAL, BRADFORD;
AND
COLIN MACKENZIE, O.B.E., F.R.C.S. Eng.,
ASSISTANT SURGEON TO THE ROYAL INFIRMARY, BRADFORD;
SURGEON TO ST. LUKE'S HOSPITAL.
With Comments by W. McAdam Eccles,
M.S. Lond., F.R.C.S. Eng.

We venture to publish this case in detail, for although many cases of traumatic hernia of the diaphragm have been recorded since 1914, yet in this case the long period of normal good health which elapsed between the trauma and the onset of symptoms renders it worthy of record.

History.—Patient served with the infantry in France, and was wounded in the left chest in 1917. As he was taken prisoner at the time of wounding no notes of his treatment are available, but he stated that he was in a German hospital for nine months, and that he had hæmoptysis for 24 hours after being wounded. In October, 1920, he was examined for life insurance, and by the courtesy of the insurance company we are permitted to publish his medical report. He was then a well-developed man of 25 years, 5 ft. 10 in. in height, and 10 st. in weight, of athletic and abstemious habits. Apart from his wound he had never had any serious illness. The size of his heart, the position of the apex beat, and the heart sounds were normal in every respect. He had a scar 6 in. long and 2½ in. wide over the sixth, seventh, and eighth left ribs; the scar was pliable, non-adherent, and no loss of muscle or bone was detected beneath it. His chest expansion was 3¾ in., and examination of his chest revealed no abnormalities. He stated that his digestion was excellent, and that his bowels were regular. A trace of albumin was found in his urine, but a specimen of urine examined four days later was found to be normal.

Treatment for Acute Intestinal Obstruction.—Apparently he remained in perfect health until June, 1921, when he was admitted to St. Luke's Hospital, Bradford, with acute intestinal obstruction. The following is a synopsis of his case-sheet.

June 16th, 1921: Excellent health until seven days ago, when he had severe pain in the epigastric region, accompanied with vomiting. The distribution of the pain spread and became most acute in the right iliac region. Pain diminished in severity two days prior to admission, and vomiting ceased at the same time. Bowels unopened for seven days in spite of three enemata. No previous attack of this nature. General condition on admission was very poor, his temperature being 100·8° F. and his pulse-rate 110. The abdomen was very distended, tympanitic all over, and liver dullness abolished. Distension was most marked in the right iliac fossa, where there was also slight tenderness. Recti muscles were not rigid, and abdominal respiration was present.

Laparotomy was performed, a right paramedian incision. There was a slight amount of free fluid in the peritoneum. The cæcum was very distended, as were all the intestines up to the splenic flexure. The appendix was normal. The descending colon was collapsed. As the man's condition was too critical to permit examination as to the cause of obstruction in the region of the splenic flexure, the wound was closed, and the cæcum was drained by means of a Paul's tube. On the 19th the bowels acted naturally; the tube was draining well. On the 21st the tube came out; patient very well. On the 23rd, temperature 104°, pulse 110. Impaired resonance over the left base posteriorly. Left pleural cavity aspirated, and 20 minims of clear fluid withdrawn. On July 4th foul-smelling pus aspirated from the left chest. Bacteriological report on the fluid: "Scanty T.B., pneumococci, staphylococci, *Bacillus proteus vulgaris*, and diphtheroid bacilli present." On the 5th eighth left rib resected, and the empyema drained. On the 18th large sloughs were escaping from the tube. On the 28th the chest was closed; bowels acting naturally and regularly since June 19th. On August 6th colostomy closed under general anæsthetic. On the 30th patient was discharged from hospital.

Readmission to Hospital for "Ptomaine Poisoning."—He remained in good health until April, 1922, when he was readmitted to St. Luke's. His case-sheet reports as follows:

April 27th: Has been very well and has followed his occupation of tailor until two days prior to admission. On the 25th he ate heartily of salmon mayonnaise, but had abdominal discomfort the same night and vomited the next morning. On admission his temperature was 99·4°, pulse 104, and respirations 24. He had a small, easily reducible hernia of the middle of the operation scar. No distension, visible peristalsis, or tenderness. Abdomen was soft No dullness of the flanks; liver dullness was present. No signs of disease in the chest were noted except dullness over the left lower lobe.

His condition was provisionally diagnosed as ptomaine poisoning. He vomited small quantities of bile-stained fluid on the day of admission. On the 28th bowels acted well after an enema; on the 29th bowels acted slightly after an enema. On May 2nd patient developed hiccough. The stomach was washed out; no residue. On the 4th bowels not acting, no pain or tenderness, abdomen tumid left side, flanks resonant; patient delirious in evening. On the morning of the 6th patient died.

Post-mortem.—There is a hole 2 inches in diameter in the middle of the left dome of the diaphragm, the edges of which were rounded. Cardiac end of stomach and whole of transverse colon had herniated through this hole, and were very adherent to the posterior wall of the thorax. Lower lobe of left lung collapsed and universally adherent. The small intestines slightly distended and congested. All other organs appeared perfectly healthy.

From the above history we conclude that the patient suffered a wound of the diaphragm in 1917, and, as frequently happens, this wound never healed. His perfect health and perfect digestion for three years after receiving the wound suggests that up to 1921 no abdominal viscus herniated through the hole. The operation in 1921 showed that only a small portion of the transverse colon was obstructed, but empyema resulted from infection from the obstructed part of the colon. The probable result of the empyema was to enlarge the hole in the diaphragm, and from adhesions rendered the herniated portion of the colon irreducible. Though the condition found post mortem must have been present for some time, for the adhesions binding the intestines to the posterior thoracic wall were very dense, yet the good health of the man between September, 1921, and April, 1922, suggests that the development was gradual, and doubtless there was concurrent compensatory development of the muscle coats of the proximal gut which masked the increasing obstruction.

Remarks by Mr. W. McAdam Eccles.

This case is of great interest from the point of view both of surgery and of examination for life insurance. There can be but little doubt that the authors' explanation of the condition is correct. Proof that a second attack of obstruction can occur is instructive, and shows that an unclosed traumatic diaphragmatic hernia is always a source of grave danger. The careful examination by the life insurance company proves the great difficulty of demonstrating the presence of such a hernia. When a man, who has been wounded through the chest, with possible damage to the diaphragm, desires to obtain a life insurance policy the examiner is confronted with the possibility of overlooking a condition, which in this particular case led to fatal results within a comparatively short time after the proposer had been accepted. It is impossible to say how many cases of unsuspected traumatic diaphragmatic hernia are in existence, but the number of men who were wounded through the chest and diaphragm and have survived probably amounts to several hundreds. Under these circumstances it becomes a question whether every such person on presenting himself for life insurance should not be examined by means of an opaque meal and X rays, which in many instances clearly demonstrates the lesion. In my paper "Lives Damaged Through the War," read in March, 1919, before the Assurance Medical Society, I overlooked the possibility of death from strangulated diaphragmatic hernia, although I considered damage to the abdominal wall producing a ventral hernia not cured by operation to necessitate rejection. A traumatic diaphragmatic hernia should obviously come under the same category, if it has been demonstrated by X rays.

THE OPERATIVE TREATMENT OF SEPTIC MENINGITIS.

By H. L. MARTYN, F.R.C.S. Eng.,
ASSISTANT SURGEON, KING EDWARD VII. HOSPITAL, WINDSOR.

Up to the time of the Tenth Otological Congress, held at Paris in July, 1922, when Mr. G. J. Jenkins read a paper on the successful operative treatment of septic meningitis occurring as a complication of aural suppuration, the condition was regarded by most as inevitably fatal. The extreme importance of Mr. Jenkins's work, following on that of Ballance and Eagleton, leads me to ask forbearance, in case the reader be already conversant with it, for free quotation from Mr. Jenkins's conclusions, for which quotation he has kindly given me permission. My object in so doing, and in reporting the subsequent case, is to bring to greater notice the undoubted value, both as regards diagnosis and treatment, of Mr. Jenkins's thesis, and to show further that operative interference can be successful even in a case of well-established meningitis, given the early recognition of symptoms and localisation of the focus of maximum infection.

Problem of Drainage.

Successful drainage of the infected area in the meninges is no more to be regarded as impossible than the successful operative treatment of peritonitis. It is true that in the former we are dealing with a far more complicated serous space, in part trabeculated and in part in the form of cisternæ, enveloping an organ of extreme delicacy; nevertheless, infection, as in the peritoneum, for a time at any rate, is localised. If this time is seized upon there seems no valid reason why drainage of that infected area, even though it be not shut off—as would be the case with a localised sub-dural abscess—should not be as successful as the drainage of a commencing general peritonitis. The main point of difficulty is unquestionably the early diagnosis of the existence of a commencing meningitis, often masked by the signs of an acute mastoiditis or labyrinthitis, and having diagnosed its existence, to localise it to trabeculated regions or cisternæ.

The fact cannot be sufficiently laboured that to look for success by operative measures necessitates diagnosis before the development of the classical symptoms and signs of meningitis. The drowsiness, occipital headache, nuchal tenderness, slight rigidity, moderate temperature, with comparatively slow pulse, absence of papillœdema, and marked cerebro-spinal fluid changes, commented upon by Mr. Jenkins as characteristic of cisterna infection, are well illustrated by the case quoted below. They will be noted in sharp distinction to the symptoms described by him as characteristic of infection in the trabeculated region over the temporo-sphenoidal lobe, as would occur in spread through the roof of the middle ear—irritability, vague headache, especially over the affected ear, higher temperature with proportionately rapid pulse, photophobia, and but slight alteration in the cerebro-spinal fluid.

Drainage Routes.

Mr. Jenkins strongly advocates the translabyrinthine route for drainage of the cisterna pontis, urging in its favour that since the internal auditory meatus is the general route of infection from the ear to the cistern, it is obviously wrong to leave this "backwater" of the cerebro-spinal system undrained.

In the first case in which I attempted drainage of the cisterna pontis for septic meningitis, following a fractured base in a child and subsequent infection through the membrane, I did not follow his suggestion, but drained the cistern by a tube passed along the back of the petrous temporal between the posterior labyrinth and the lateral sinus. A free flow of turbid cerebro-spinal fluid resulted, all pressure signs disappeared, and the child improved for a time, but died subsequently from a generalised lepto-meningitis. Post-mortem examination proved the soundness of the translabyrinthine route, in that while the drain lay perfectly in the cisterna pontis, the fissure and route of infection lay through the internal auditory meatus, and this and the neighbouring bone were full of purulent and undrained exudate.

In the case quoted below the actual route of infection is obscure. There is no doubt that the primary focus of infection was in the cisterna pontis, but neither then nor subsequently was there any sign of labyrinthine involvement, and it appeared reasonable to suppose, in view of the stormy course after the mastoid operation, either that the infection was without involvement of the internal ear, or that it was in the nature of a "fixation area" in a generalised septicæmia. Under these circumstances it did not seem justifiable to drain via the internal auditory meatus, and as a very prominent lateral sinus coming close up to the posterior labyrinth rendered the alternative route difficult, I preferred to drain the cisterna pontis by a horizontal incision through dura below the lateral sinus, immediately behind its point of curvature downwards. This gave an admirable access and by lifting the cerebellum gently with a narrow flat spatula I induced a free gush of turbid cerebro-spinal fluid from the cisterna, which continued easily along the drain. At the same time a drain was introduced, through an incision in dura and arachnoid above the sinus, forward to the region of the Sylvian fissure. This was probably unnecessary, as the symptoms were certainly those of cistern infection rather than of temporo-sphenoidal infection.

The clinical reports (by Dr. E. C. Malden) on the two subsequent specimens of cerebro-spinal fluid withdrawn by lumbar puncture are interesting, as illustrating Mr. Jenkins's statement that although the symptoms of meningitis may be relieved at once, as they were in this case by drainage, the latter must be maintained until it is obvious by examination of the cerebro-spinal fluid that the infection is checked, which evidently did not occur here until between the sixth and ninth days after operation.

A female, married, aged 37, was admitted to King Edward VII. Hospital on Dec. 31st, 1922, with a history of influenza, followed by pain in right ear and discharge on day preceding admission. On admission: Temp. 99° F.; pulse 100; profuse purulent discharge of right ear through an antero-inferior perforation; general mastoid tenderness; œdema of posterior meatal wall; no nystagmus; reflexes normal.

Operation.—A Schwartze operation was performed on the right mastoid. Free pus in antrum and air cells; very cellular type of mastoid with prominent lateral sinus and deep antrum. Operation at night; no bacteriological examination. On Jan. 1st and 2nd, 1923, temp. rose to 101°; no adverse symptoms except considerable nasal catarrh and some frontal headache. On the 3rd, temp. normal all day; no evidence of actual sinusitis. Inhalations of menthol relieved headache. From the 4th to the 7th, temp. fluctuating 102°–103° at night, normal in morning. Wound dressed, clean; aural discharge ceased. No alteration in reflexes, no vertigo or nystagmus, no occipital pain, headache ceased. From the 8th to the 11th temp. progressively falling to normal. Patient better. A blood count on the 8th showed 11,200 leucocytes per c.mm. On the 12th, temp. normal all day; mastoid wound very clean. Membrane healed. Blood culture, taken subsequently, proved negative. From the 13th to the 16th temp. rising to 100° at night; no adverse signs; patient taking food well. No headache. On the 17th temp. normal all day. On the 18th temp. in morning 97·4°. Condition not so satisfactory. Patient drowsy and complaining of vaguely localised headache. Late at night temp. rose to 100°, pulse 104. Patient complaining of more severe and more localised occipital headache. On the 19th, occipital headache bilateral and severe, nuchal tenderness, slight but definite rigidity, temp. 101°, pulse 110. Knee-jerks +, and plantar reflexes normal, abdominal reflexes present except upper right quadrant; patient vomited once; no vertigo; nystagmus to left, pupils equal and active, discs normal.

Lumbar Puncture.—Fluid not under pressure but turbid. Cell count 7200 per c.mm., the majority polymorphonuclear leucocytes; a few Gram-positive diplococci seen; culture subsequently sterile; no reducing substances present.

Second Operation.—Mastoid incision extended by horizontal incision backwards and flaps turned up and down. Mastoid wound clean, but with little or no reaction. Bone removed over a wide area upwards from mastoid cavity to expose outer surface of temporo-sphenoidal lobe and backwards and downwards exposing lateral sinus and dura below tentorium.

Free hæmorrhage from lateral sinus emissory vein. Sinus normal. Wound washed out with iodine. A few minims of fluid withdrawn by hypodermic needle from subarachnoid space of middle fossa and also from that of posterior fossa below lateral sinus. The former subsequently proved sterile, but that from the posterior fossa was turbid, and showed a few of the same Gram-positive diplococci observed in the cerebro-spinal fluid (C.-S.F.). Subsequent culture was sterile. An incision was made in the dura and arachnoid over the temporo-sphenoidal lobe, and a gauze drain wiped over with bipp was passed forward to the region of the Sylvian fissure. A similar but larger incision was made in the dura below the horizontal part of the lateral sinus. A narrow spatula was passed in gently below and in front of the cerebellum to the cisterna pontis. A free gush of C.-S.F., turbid and under pressure, resulted, and continued freely along the gauze drain introduced. The wound was packed lightly with bipp gauze and dressed.

Subsequent Progress.—Immediately after operation temperature fell to normal, all headache and rigidity disappeared, nystagmus to left increased and also appeared in upward direction. On Jan. 22nd the wound was dressed. Patient very much better, no symptoms whatever. Lumbar puncture repeated. Fluid under low pressure, less turbid; cell count 6500 per c.mm.; no bacteria seen; no reducing substances present. The drain in the middle fossa was removed, that in the subtentorial area removed, and replaced with free flow of C.-S.F. On the 25th wound again dressed. Patient very well; temp. had remained below 99°. Lumbar puncture repeated; fluid under low pressure, almost clear; cell count 130 per c.mm.: no bacteria seen; slight reduction of Benedict's solution. Wound clean, all intradural drains removed. On the 29th wound again dressed. Covered with commencing granulation tissue. Temperature and pulse normal, patient very well. Complaining of no symptoms, sleeping and eating well. Feb. 1st, progress uneventful. Wound clean and granulating rapidly.

I am much indebted to Dr. E. C. Malden for the clinical reports from the pathological laboratory, King Edward VII. Hospital, Windsor.

SUPPURATIVE ARTHRITIS SIMULATING ACUTE APPENDICITIS.

By J. ALLAN BERRY, M.S. Durh.,
F.R.C.S. Edin.,
SUPERINTENDENT, NAPIER HOSPITAL, NAPIER, NEW ZEALAND.

THE following case of suppurative arthritis of the eleventh right costo-vertebral joint simulating acute appendicitis seems worthy of record, since, as far as I am able to learn, nothing similar has been previously reported.

The patient, a well-nourished girl of 9 years, had been a breast-fed baby. When a few months old she suffered from bronchitis; at the age of 3½ years she had measles, at about 7 whooping-cough, and shortly afterwards was in hospital for about nine weeks suffering from scarlet fever. Since then she had never quite recovered her former strength, and had suffered from frequent whitlows, although she had had none during the past year. Between six and eight months ago a large abscess appeared in the right groin, which discharged for some time.

On Feb. 27th, 1921, the child, after returning home from a walk, stated that she had tripped in a hole and had hurt herself. There was a slight abrasion over the upper part of the right tibia, and she complained of pain in the right hip. For the rest of the day, and on the 28th, there was no complaint of pain. On the morning of March 1st she ate a good breakfast, but on returning from school about 5 P.M. had a shivering attack. The mother noticed she was feverish and gave her a purgative. On the morning of the 2nd the child was unwell, and had very little food all day. About 10 o'clock in the evening she complained of pain in the abdomen, and of a slighter pain in the right hip, and spent a restless night. On the 3rd the child said she felt better, but a doctor was called in about mid-day. Her temperature was then 101° F., pulse rapid, respirations not increased disproportionately, and she complained of pain in the right loin. She was tender in that region, and also over the right ileum, so much so that the diagnosis of an osteomyelitis of that bone was considered by the doctor in attendance. At 6 P.M. the same day the temperature had risen to 103°, the pulse was more rapid, and the tenderness had become more widespread, affecting the area over the right iliac fossa, and appearing also over the lower ribs. There was no history of vomiting. She was admitted to Lewisham Hospital about 9 P.M. as an atypical case of acute appendicitis, the preceding more detailed history being obtained later.

Condition on Examination.—The child looked ill, and it was difficult to examine her properly on account of her irritability. All the pain was referred to the right loin. There were no signs of trauma in this region. The whole of the right side of the abdomen was found to be rigid and tender, the tenderness extending from the lower ribs above to the great trochanter below, and limited by the mid-line in front. The thigh was flexed slightly, and internally rotated. The right erector spinæ muscles were rather spastic. The hip-joint appeared normal. A pelvic examination and an examination of the urine revealed nothing abnormal. Examination of the lungs showed nothing abnormal, and the respiration-rate was not unduly increased. The reflexes were slightly exaggerated. The anomalous physical signs led to a suspicion of an osteomyelitis of the spine, and this diagnosis was carefully considered, but in view of the good mobility and absence of tenderness on pressure over the spinous processes it was excluded. A possible diagnosis of a retro-cæcal or lateral cæcal inflamed appendix with an abscess lying in front of the right kidney was made.

Operations.—Under light open ether anæsthesia I made a muscle-splitting incision at a higher level than usual. The appendix was found along the outer side of the cæcum, adherent to it in its first part, but free in its distal portion and perfectly normal in appearance. As this organ obviously could not be the cause of the symptoms the remainder of the abdomen was rapidly examined and nothing abnormal was found. The appendix was removed and the abdomen closed. On the morning of the 4th the temperature had fallen, although the child still looked ill, and during the day she became much worse, being incontinent and delirious, complaining constantly of pain in her right side. During the night of the 5th, the temperature rose rapidly until it reached 105·8°. At that time the abdomen was as rigid as before the operation, and somewhat distended. On examining the urine again it was found to contain a large amount of acid products as tested by the ferric chloride reaction. The reflexes were still normal, but there was slight head retraction, so a lumbar puncture was performed. The cerebro-spinal fluid was not under pressure.

On the 6th some slight moist sounds were heard at the lung bases, and the abdomen seemed more lax. The child was much worse, although there was a considerable diminution in the amount of acid products excreted. On the morning of the 7th the patient was delirious. An intravenous infusion of sodium bicarbonate was given, which led to a dramatic improvement, but this was not maintained, and the child died, about 11 P.M., in coma.

Post-mortem.—Dr. T. C. Higgins and I performed an examination on the following day. There were some hypostatic congestion at both lung bases and a few small areas feeling like infarcts. Microscopical sections confirmed this, and cultures gave a pure growth of *Staphylococcus aureus*. In the left pleural cavity was a small semi-translucent mass of greenish lymph, which showed on microscopical examination a few leucocytes and on culture gave numerous colonies of staphylococci, and on liquid media a few of *Streptococcus longus* also. In the right pleura were a few drachms of clear fluid. The heart muscle showed some cloudy swelling and dilatation, but was otherwise normal. The stump of the appendix was clean and healing, and nothing abnormal was found in the remainder of the abdomen. Hip-joint, brain, and spinal cord were normal. Outside the spinal dura, over the foramina of the tenth and eleventh intercostal nerves and vessels in the right side, a small quantity of thick whitish pus was found, and where it lay in contact with the dura there was slight pachymeningitis, but no evidence of inflammation could be seen from the inner aspect.

On stripping off the pleura in the right side we found that the anterior part of the capsule of the eleventh costo-vertebral joint had been eroded, and that the head of the rib could be pushed forwards considerably by pressing in the cut sternal extremity, showing that the remainder of the capsule had also been destroyed. In the intercostal space above and below, pus could be seen shining through the posterior intercostal membrane. The total amount of pus present did not exceed at the most two drachms. Direct examination of the pus showed Gram-positive cocci, and culture gave colonies of *Streptococcus longus*. No thrombo-phlebitis was noted in the intercostal veins. On removing the eleventh vertebra with its attached ribs we found the middle costo-transverse ligament on the right side to be partially separated, due to the tracking of the pus. The cartilage on the vertebra itself was eroded, while that on the head of the rib was intact. Section of the body of the vertebra showed no sign of suppuration. The remaining bodies and costo-vertebral joints were examined and found to be normal.

On looking back over this case, it is possible that a correct diagnosis might have been made in the earlier stages, although even then the pain appears to have been located not at the seat of trouble, but mainly in the distribution of the tenth and eleventh thoracic nerves. As the area over McBurney's point is supplied by the eleventh nerve and the appendix receives filaments from that nerve and possibly from the tenth, a diagnosis of appendicitis would have to be considered. It is interesting to note that although the tenth and eleventh nerves in this case were involved primarily, yet there was an "overflow" as explained on physiological grounds, leading to hyperæsthesia of the nerves above and below.

The fact that the child was liable to septic sores, abscesses, &c., suggests a chronic bacteriæmia from some septic focus, possibly her tonsils, although she never suffered from sore-throats. In the fall on her side it is possible that the brunt of the shock came on the eleventh right rib and injured the cartilage on the synovial membrane of the joint, leading to a synovitis which suppurated, or perhaps to an osteomyelitis of the vertebral body just deep to the cartilage, leading clinically to the same result.

On looking through the literature, I have been unable to find a similar case. Makins and Abbott, in 1896,[1] collected cases of acute osteomyelitis of the spine, some with secondary involvement of the costo-vertebral joints. Subsequent to this a few cases of acute osteomyelitis of the spine are reported in various papers, but the costo-vertebral joints are not mentioned. In 1915 Volkmann collected 62 cases, and in 1918[2] Schlesinger collected a number of additional cases. Recently Plenz[3] has reported two cases of acute osteomyelitis of the spine, but in none of these is a primary suppuration in the joint dealt with. It seems extremely probable that cases similar to the one I have reported are not so excessively rare, since during life diagnosis may be impossible and post mortem the lesion may very easily escape notice.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ANÆSTHETICS.

A MEETING of this section was held on March 2nd, Dr. A. L. FLEMMING, the President of the section, being in the chair.

Dr. W. J. McCARDIE (Birmingham) read a paper on

GENERAL ANÆSTHESIA IN ORDINARY DENTAL PRACTICE.

He said the administration of anæsthetics in dental work differed from that in ordinary surgery in that it was more intimately concerned with the mechanics of respiration, and because the patient usually had had no special preparation before the administration, and was mentally alert, bodily active, often very nervous and critical of his surroundings. Dr. McCardie considered that when all or a considerable number of teeth needed to be extracted everything possible should be done at one sitting, and this was preferred by the patient in most instances. In former days extractions were done almost entirely for pain or local disease; but now toxic conditions and root diseases required a more prolonged anæsthesia. For many years he had regarded nitrous oxide as the main anæsthetic in dental practice; and he had had no fatality during anæsthesia, nor had to use his tracheotomy set. One case in 23 required a major anæsthetic—ether or chloroform—solely or mainly. Of 91,734 anæsthesias given between 1896 and 1922 in the hospital to which he was attached, 3500 were ethyl chloride, 200 ether, 88,000 gas alone. No oxygen was given. No deaths were recorded either during or after anæsthesia. No fatality nor even tracheotomy had occurred during anæsthesia in the life of the Birmingham Dental Hospital, a matter of 40 years. In a large proportion of the 100,000 gas cases the anæsthesia was carried out by students, a fact which showed it was a safe administration. Students at the hospital were taught no anæsthesia except nitrous oxide. Gas and oxygen combined, unless exceptionally well administered, he regarded as of comparatively little value in dental work. One set of American statistics gave two fatalities in over a million cases.

The Choice of Anæsthetic.

The choice of the anæsthetic depended on the type and duration of the operation; his preference was nitrous oxide with or without a very small quantity of ether. If a patient suffered from serious heart or lung troubles or toxic diseases, gas and oxygen seemed best. During the war nitrous oxide was found not to suffice for soldiers; it was best to treat them as major surgical cases, preparing them overnight, and giving morphia and atropine beforehand, then ether, followed if necessary by chloroform. For young children he found prolonged gas and oxygen best. Induction took from one to three minutes. Ethyl chloride upset them too much. If patients bore gas badly they were but little upset by a major anæsthetic. There might be dilatation of the heart in the absence of cyanosis. Sometimes the physician still told the anæsthetist what form to use, a matter which was outside his province. When people required their teeth extracted at a sitting they should go to a nursing home for the purpose. Ether, Dr. McCardie considered, was as safe as gas for dental surgery. In many prolonged cases he believed the substitution of ether for gas would have resulted in less shock to the patient; the shock was generally felt most after reaching home; if he could have been put straight to bed this might have avoided any shock. One patient, aged 55, had been under treatment for high blood pressure. He was given gas for the extraction of two teeth; he appeared healthy and was of good physique. He died five hours after the operation from coma. That was the only death in connexion with dental administration he had ever come across. For very nervous people a dose of bromide on the night previous to the operation was very useful. Aspirin was not advisable as it tended to cause cyanosis. For giving immediately before the anæsthetic, brandy or whisky were the only sedatives which should be considered. If a patient turned grey or blue, ether proved a good stimulant. An etherised sponge gave a gas-and-oxygen effect. For dental work the Ormsby inhaler was far better than the Clover, because any quantity of ether could be poured into it and the deepest anæsthesia quickly occurred. In the case of small children or obstreperous adults who would not breathe as directed he applied the Ormsby straight away. Ether caused less after-effects than did ethyl-chloride. For major dental cases, after deeply etherising, he continued with light chloroform anæsthesia. Respiratory trouble, caused by depression of the jaw and pushing back the tongue during operations on the lower teeth, could be overcome sometimes by the use of a mouth tube. On coming round, patients should not be allowed to see a bright light as it hastened the return to consciousness, and this might be accompanied by excitement. On two occasions teeth had slipped into or in the neighbourhood of the larynx. One coughed up the tooth after a violent spasm soon afterwards; the other did not eject it for two days. He also related two cases in which severe bleeding followed extractions. In one it came from a plexiform angioma or a cirsoid aneurysm.

Summarising his conclusions, Dr. McCardie said: (1) Dental operations should be concluded at one sitting, even if it meant resorting to a major anæsthetic; (2) nitrous oxide, being the prolonged method, was the best routine anæsthetic for qualified men and students; for difficult cases, deep ether followed by light chloroform anæsthesia was best; (4) major cases should be dealt with only in hospital; (5) ether from an Ormsby inhaler gave the best results in the case of children and troublesome adults; (6) shock after long dental operations under gas developed mostly as the result of asphyxia, and the addition of a little ether during the anæsthesia would greatly improve the condition of the patient.

Discussion.

The **PRESIDENT** said he did not feel so keen as Dr. McCardie did about getting the dental treatment done with one administration. But he was sure the opener's attitude was dictated by his desire to do his best for the patient. An interesting point was the comparison of the value of air as against oxygen.

Mr. **WARWICK JAMES** showed an instrument he had devised for fixing the mandible forward, thus preventing it from dropping back while the patient was under general anæsthesia, and so restricting respiration. While he was working at the Great Ormond-street Children's Hospital for ten years, ethyl chloride was found to be the best anæsthetic for the young patients, even for dealing with a large number of teeth, especially if the dentist kept the mandible forward.

Mr. **CARTER BRAINE** was pleased to hear the Ormsby inhaler praised; for all severe and prolonged dental operations he relied upon it. If the majority of the teeth to be extracted were in the lower jaw it was best to have the patient seated. To keep the head rigid Mr. James and he had devised a horseshoe-shaped cushion filled with sand. He did not think sufficient care was taken to prevent teeth being swallowed or inhaled during extraction; this was a bounden duty on the part of the dentist.

Sir **FRANK COLYER** said it should always be the dentist who ought to decide how many teeth should come out; and he did not agree that a dental operation should always be completed at one sitting. Especially in the case of dental sepsis the best procedure was to extract a small number at a sitting. The dentist should have in his mind that every second during which the patient was under the anæsthetic was a time of danger. Continuous gas was not a good anæsthetic for a prolonged dental operation; but it was useful for operations of short duration, and under it the dental surgeon felt he had a little longer for his operation than under gas. If there was likely to be any difficulty about removing the teeth the patient should be taken to a nursing home for the purpose. He was sure it was right to plug the pharynx. Some patients took gas very badly; he had had patients who suffered from a kind of syncope after it; it acted on them almost as a cardiac poison, and he would like to know how this type could be recognised beforehand. Oxygen led to distress in some patients. People with a high blood pressure should have gas and oxygen, he thought.

Mr. **H. BELLAMY GARDNER** insisted on the value of adhering to one method of administration on all possible occasions, as it taught efficiency and enabled one to know exactly what one could do. Nitrous oxide and oxygen anæsthesia could be maintained practically indefinitely. For prolonged cases, however, for which ether had been decided on, he gave gas and ether, and continued with chloroform. In the case of powerful men who required six or seven teeth removed, he gave 1/6 gr. morphia half an hour before the operation; this rendered the gas and oxygen anæsthesia comfortable and free from dreams. The sitting posture was best, but practically no nursing home in London had a dental chair always available. He fully agreed with what had been said about the value of brandy.

Mr. **H. BOYLE** did not agree as to the need for completing a dental operation at one sitting. He had been giving gas and oxygen for 20 years; it caused less of that feeling of suffocation which many who had gas alone complained of. If the dentist required extra time he continued with gas alone, while the patient breathed air through the mouth. Prolonged gas administration was a great boon to the dentist as it enabled him to do his work more leisurely. He quite agreed it was not within the province of the physician to suggest the kind of anæsthetic; indeed, the majority of physicians knew very little about anæsthetics. Certainly a long and difficult case should be taken to a nursing home.

Mr. **F. COLEMAN** spoke of the improvement in the operations in dental cases due to the fact that the anæsthesia was now more prolonged than formerly, and to the better opportunity for developing the sense of touch, by which one felt instinctively how much strain a particular tooth would safely stand.

Dr. **H. HILLIARD** thought the extraction of six or eight teeth should be regarded as a major operation, and should only be done either in the patient's home or in a nursing home. He was a warm advocate of ethyl chloride as an anæsthetic.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

OBSTETRICAL SECTION.

Exhibition of Cases and Specimens.

A MEETING of this section was held on Feb. 23rd, Dr. **BETHEL SOLOMONS**, the President, being in the chair.

Dr. **R. E. TOTTENHAM** exhibited a modification of the Rotunda syphon douche, which he stated was cheaper than the Rotunda syphon douche, and had the advantage that if any part of the rubber gave way it could be renewed without purchasing a whole new douche. Smith and Sheppard were the makers.

Sir **ANDREW HORNE** showed two specimens.

Malignant Ovarian Tumours; Fibrocystic Tumour. It was very rare, he stated, to find two large ovarian tumours in the same woman; the patient, aged 46, had had one child five years previously, and had menstruated perfectly regularly up to May, 1922. She then missed two periods, but had been regular since. She was sent up to consult Dr. P. McArdle, as a case of doubtful pregnancy, but was herself convinced that she was pregnant. She was found to have a cystic tumour. An operation was performed; the two tumours filled the abdomen, and at the upper portion of the abdomen there was some ascitic fluid. William Colles had pointed out that, when a tumour was found with ascitic fluid, it generally indicated malignant disease. In the second case a woman, aged 46, had been married one year; just before she married menstruation had ceased, although she had always been perfectly regular. She complained of soreness in the chest at both sides, hardness in the abdomen, and a frequent desire to micturate. On vaginal examination he found that the body of the uterus was displaced, and the cervix could only be reached with the greatest difficulty. The tumour could apparently be pushed away from the uterus. On operation the tumour proved to be a subperitoneal fibroid, which grew from the lower edge of the cervix uteri. The patient made an uneventful recovery. The tumour was not malignant.

The **PRESIDENT** said that the diagnosis of double ovarian tumours and twins was always easy as the tumours were plainly palpable in most cases. In the fibrocystic tumour he (Dr. Solomons) wished to know if a pre-operation diagnosis was made as it seemed impossible.—Dr. **D. G. MADILL** asked what the pedicle consisted of; if it was an enlarged or elongated cervix, or if it was the vagina drawn up. Dr. **W. D. O'KELLY** asked if, in the first case, there was any glandular involvement.

Sir **ANDREW HORNE** replied that in the second case he thought he was going to operate on a case of ovarian tumour, and was therefore surprised to find a large fibrocystic tumour in the uterus. The pedicle was very short, thick, and solid, made up of fibromatous tissue and attached not to the uterus but to the super-vaginal portion of the cervix. In the first case there was no evidence of external glandular enlargement, but he did not know what was found at the operation, as he was not present. He was inclined to think that the tumours were both primary, and not secondary.

Septic Uterus.

Dr. GIBBON FITZGIBBON showed a specimen of a septic uterus. The patient was sent into hospital after being four days in labour. The child was alive. On admission patient's temperature was 98° F., but it gradually fell to 95·4°. The pulse was 100 and remained at that till the patient died. In answer to a question from Dr. H. E. GOULDING, Dr. FITZGIBBON stated that there had not been time to get a blood examination carried out.

Dr. A. H. DAVIDSON read a paper on a case of

Traumatic Subcutaneous Emphysema Complicating Labour.

Dr. FITZGIBBON said that he had seen this patient with Dr. Davidson, and the condition was one of great interest. He thought that Osler's explanation of emphysema was the best—namely, that it arose from a rupture of the bronchi in the mediastinum.—Sir ANDREW HORNE said that he had seen three or four similar cases. Labour had been very severe during the second stage with severe uterine contraction. On the second day there was a regular crackling under the skin. No treatment was adopted, but at the end of eight or nine days the emphysema had disappeared. He agreed with Dr. Fitzgibbon regarding the cause of emphysema.—Dr. DAVIDSON, in reply to a question from Dr. MADILL, said that the patient had had no cough.

Dr. L. CASSIDY read a paper on a rare case of maldevelopment of the female genital organs, and showed specimens.

Deep X Ray Therapy.

Dr. G. E. PEPPER read a paper on this method, as used in the Schauta Klinik, Vienna. He described the "Symmetrie" apparatus devised by Prof. Seitz and Wintz, of Erlangen, the various instruments used for measuring the dosage, and the method of estimating penetration of rays by means of the water phantom. He referred to the importance of accurately centring the tube in each field, the susceptibility of different patients to radiation, and the necessity of a blood count before each treatment, and described the Vienna method of treating carcinoma of the uterus, and the application of X rays in cases of essential bleedings, amenorrhœa, and fibro-myomata. He compared X rays with radium in the treatment of malignant disease, and advocated the combined use of both. The action of X rays on malignant cells was said to be due to ionisation, which causes lecithin to split up and liberate cholin which poisons and kills the cells. Cholin is set free in the very cells where its action is required, because malignant cells and tissues particularly sensitive to X rays, such as testicles and ovaries, contain higher percentages of lecithin than other tissues.

Dr. W. C. STEVENSON thought that as much constitutional disturbance occurred when X ray and radium treatment was given as after an operation, but that one treatment only did not give a patient a proper chance. If the growth was extensive there was a chance of increasing it by radiation unless deep X ray therapy was used.—Dr. L. L. CASSIDY thought that any fresh advance in the treatment of cancer would be made by X rays. His experience in hospital regarding radium had been rather unfortunate; in two cases its application had appeared to stimulate the growth, although in another case of inoperable carcinoma the patient was very much improved.—Sir ANDREW HORNE remarked on the effect of X rays in stopping hæmorrhage, and asked how it was known clinically that X rays had destroyed cancer cells.—Dr. MADILL asked if moderate doses of X rays would have any effect on an old-standing case of pelvic cellulitis.—Dr. J. F. CUNNINGHAM asked how the radium was filtered before insertion into the uterus, and whether radium emanations were of any use.—Dr. G. TIERNEY said that according to Erlangen technique, an eight-hour dose of X rays was not strictly correct; in Erlangen Coolidge tubes were now used exclusively, and the unit skin dose was obtained in a little over 20 minutes. In some cases constitutional reaction was severe, but never as severe as after operation. Generally speaking, the indications and contraindications for radium and X ray treatment were exactly similar. The advantage radium had over X rays was that screening was much more effective.—The PRESIDENT said that the present state of affairs with regard to treatment of cancer was a race between radiology and serums; operative treatment, combined with one of these, would probably win. He had read of collapse and anæmia following the Erlangen treatment; his feeling was that when a growth had been satisfactorily eradicated post-operative X rays were dangerous.

Dr. PEPPER said, in reply, that constitutional effects were undoubtedly produced after the application of X rays, but they did not last; patients were often able to return home in two or three days. In some cases, after treatment was over, a small operation had been performed, and it had been found that the cancer cells had been destroyed by the X rays. He could not tell what the result of X ray treatment would be in a case of pelvic cellulitis. Emanations were not used in Vienna, as they had a considerable stock of radium. Gas tubes were there used entirely, as they were much cheaper than Coolidge tubes.

NEWCASTLE-UPON-TYNE AND NORTHERN COUNTIES MEDICAL SOCIETY.

A MEETING of this Society was held in the Royal Victoria Infirmary, Newcastle-upon-Tyne, on Feb. 1st, when Mr. D. P. D. WILKIE delivered an address on

Diagnosis in Surgery.

The address was a plea for the coöperation of practitioner, physician, and surgeon in the interpretation of early symptoms of disease. Mr. Wilkie said that our greatest need at the present time was for surgeons who knew *when* to operate rather than *how* to operate. The advances in surgery in the next decade would surely be in the accurate and timely diagnosis of the conditions which we had now learned to treat by surgical means. Diagnosis was the crux of modern surgery, and the increasing success of the latter was due, in his opinion, to the improved diagnoses of the general practitioner.

Mr. Wilkie then enlarged upon what he considered to be the fundamentals of diagnosis. He placed first clinical instinct, which came naturally to the few, but to the majority was the outcome of prolonged, purposive and careful observation. The surgeon had a peculiar asset in the training of his diagnostic acumen in that so often he could lay bare the true pathology after having studied the signs and symptoms. The physician and practitioner might to some extent share this advantage by systematic attendance at operations on their cases. Next to clinical instinct, Mr. Wilkie put clinical history. The interpretation of symptoms was a problem which urgently required the coöperation of all branches of the profession. Complete physical examination was the next essential. There was a noticeable advance of lay opinion towards a recognition of the benefit of full investigation before operations for chronic maladies. The time, trouble, and expense involved were all well spent in the accurate guidance obtained and the possible avoidance of an unnecessary or a purely experimental operation.

If an accurate diagnosis was to be arrived at, full use must be made of the accessory or special methods of diagnosis. Some of these were simple and capable of almost universal application; others required special training, as the Wassermann test. Exploratory operations on the urinary tract must now never be considered until cystoscopic examination, catheterisation of the ureters, and pyelography had all been employed. Estimation of renal efficiency was of great value in sifting out the safe from the hazardous surgical risks, and the estimation of blood-urea was now becoming practically routine before the operation of prostatectomy. The use of the basal metabolism test now enabled us not only to diagnose when cardiac symptoms were due to thyroid hyperactivity, but also whether the nervous state of the patient was merely neurasthenic, or is due to poisoning by thyroxin. It was also a valuable guide as to the nature and extent of operative interference which the patient would stand with safety. The faint trace of jaundice, only with difficulty detected in the skin and eye, which accompanied the early dyspeptic attacks associated with cholelithiasis, was readily shown by a simple blood test. If 5 c.cm. of blood were drawn into a syringe containing 1 c.cm. of sodium citrate solution to prevent coagulation, the mixture centrifuged and the serum pipetted off, the latter would give with nitric acid the fine play of colours familiar in the test for bile in the urine. This test was frequently positive when no jaundice was detectable, and was valuable evidence of slight biliary obstruction. The duodenal tube was a simple and fascinating method of investigating the rate and nature of the biliary discharge. Mr. Wilkie dealt at some length with the uses of radiology but deplored the tendency to rely on such evidence in opposition to clinical findings.

MIDLAND MEDICAL SOCIETY.

Exhibition of Cases and Specimens.

A MEETING of this Society was held in the Medical Institute, Birmingham, on Feb. 14th. Dr. C. E. **PURSLOW**, the President, took the chair.

Dr. G. H. **MELSON** showed a man who had complained of severe pain in the left side for several months. This man had been seen by several surgeons and physicians without a diagnosis being made. X ray examination was negative. The pain was eventually found to be due to a loose costal cartilage on the ninth rib, which was removed, and a complete cure resulted. This case was discussed by Dr. **WARDEN BRIGGS** and Dr. O. J. **KAUFFMANN**.

Dr. **LEONARD PARSONS** described a similar case following an accident, in which the fourth costal cartilage was separated from its rib, causing severe paroxysmal pain. This case recovered without operation.

Dr. **PARSONS** showed a case of "Pink Disease." He gave a short résumé of the literature of the disease, and stated that he had seen six cases. All the cases had suffered from the condition for many weeks, but previous to the onset of the disease had been well nourished and healthy children. The out-standing symptoms in this series of cases were: (1) The presence of a rash varying in degree and character but always accompanied by intense itching; (2) red, swollen, and cold feet and hands, showing desquamation; (3) striking mental changes, the patient often presenting a picture of the most intense misery; (4) gingivitis and stomatitis with falling out of the teeth; (5) a varying degree of hypotonia and pseudoparesis; (6) the frequent occurrence of respiratory disorders; (7) the liability to sudden death.

Dr. **KAUFFMANN** showed the organs from a case of lymphadenoma. Blood films and microscopic sections from the same case were shown on the epidiascope.

Dr. J. G. **EMANUEL** read a paper entitled the Treatment of Auricular Fibrillation by Quinidine Sulphate.

Reviews and Notices of Books.

DISEASES OF THE SKIN.

A Manual for Students and Practitioners. By ROBERT W. MACKENNA, M.D., B.Ch. Edin., Hon. Dermatologist, Royal Infirmary, Liverpool. London: Baillière, Tindall and Cox. 1923. Pp. 451. 21*s*.

THERE are few subjects among the special branches of medicine so well served in the matter of text-books as dermatology, and yet, with the exception, perhaps, of neurology, there is none which appears to offer more difficulties to the average student, nor of which the general physician or surgeon is more frequently ignorant. Diseases of the skin have been regarded in the past as something apart, the poor relation or, as Dr. A. Whitfield puts it, the Cinderella of the special medical sciences; we suspect that the real reason is not, as some maintain, that the nomenclature is so complex and unscientific, but that an "eye" for skins is at least as rare as an "ear" for music. The lines, however, along which dermatological research is now being directed are tending to bring the subject more and more into direct relationship with general physiology and pathology, and it is as necessary for the physician of to-day to have some knowledge of the ætiology of the more important diseases of the skin as it is for the dermatologist to keep abreast of the advances that are being made in general medicine.

Dr. MacKenna has written a book which in many ways is quite different from any other text-book of skin diseases that has yet appeared either in this country or abroad. It is pleasantly free from the hackneyed and stereotyped text-book "form," and the author has arranged the subject-matter in a manner essentially logical and practical. After two short but adequate chapters on the anatomy and physiology of the skin, the morphology of its different lesions, and the clinical examination and general treatment of its diseases, he wisely deals first with the pyogenic infections, so that the student at the outset makes the acquaintance of eruptions which are not only very common, but of which the cause is known with certainty. No account is given of multiple abscesses of young children, or of the "*hidrosadénites*" of the axilla, both of which conditions are sufficiently common to merit inclusion. The chapter on tuberculosis of the skin is good and well illustrated. In the section on the treatment of lupus vulgaris, the author states that, while disappointed with tuberculin, he is obtaining promising results with injections of sodium morrhuate, and he speaks highly of Dr. H. G. Adamson's method of local painting with the liquid acid nitrate of mercury, the value of which has been recognised by most English dermatologists. Syphilis is dealt with adequately and clearly, and the tabulation of the differential diagnostic points between various syphilitic lesions, and the eruptions they imitate should be of value to students. We think, however, that the course of intravenous injections of neosalvarsan recommended is dangerous even in healthy subjects, namely, 10 injections—0·45 g., 0·6 g., and six 0·9 g. at weekly intervals, and two more 0·9 g. after an interval of 14 days—i.e., a total of 8·25 g. over a period of 12 weeks. The risk of damage to the liver with such an intensive course is surely considerable, and we are not convinced that any advantage is gained over the method advocated by Dr. Whitfield, whereby three full doses of 0·9 g. are given at intervals of three weeks, and, if necessary, repeated according to the indications of the W.R.

In a chapter on "Skin Diseases due to a Filter-passing Virus," Dr. MacKenna includes molluscum contagiosum, verruca vulgaris and plana, and the venereal wart. The work of Kingery and Wile would seem to have established that molluscum is caused by a filter-passing organism, and the same is probably true of the common and plane wart, but the investigations of Civatte and Favre suggest that the venereal wart is due to the spirillum which is constantly found in them. The account of the erythemata is preceded by a chapter on focal infections and protein sensitisation, and a brief description is given of the method of performing the cutaneous tests with foreign proteins. In discussing the ætiology of erythema nodosum, the author rightly, we think, rejects the theory that it may sometimes be of tuberculous origin, and favours the view that a streptococcal infection is the cause: he also points out that one attack does not, as some have asserted, confer immunity, although recurrences are not frequent. Lupus erythematosus he includes among the erythemata, and adduces convincing arguments against it being considered as a tuberculide: "No disease," he says, "in the whole range of dermatology has a more unfortunate name than that generally known as lupus erythematosus." In the brief description that is given of keratodermia blenorrhagica, it is suggested that some of the cases reported have really been syphilitic or psoriatic hyperkeratosis in a person suffering from gonorrhœa. In view of the disappointing results that many have experienced with collosol manganese, it is interesting to note that Dr. MacKenna is enthusiastic about it in the treatment of suppurative acne. He prefers the freshly prepared solution, obtained by mixing equal parts of No. 1 and No. 2 solutions, and he gives six injections subcutaneously at intervals of four days in doses increasing from 0·5 c.cm. to 2 c.cm., the course being repeated at the end of a fortnight if necessary. In the section on malignant tumours of the skin, no mention is made of the very superficial, usually multiple form of basal-celled carcinoma that is apt to be wrongly diagnosed as psoriasis or seborrhœic dermatitis; and in the description of Paget's disease of the nipple, the author accepts Sampson Handley's view that it is always secondary to malignancy in the breast. This will not be universally accepted among dermatologists.

It is clear the book has been written largely from the author's personal experience, and it is therefore easy and attractive to read. Although there are no coloured plates, the illustrative photographs are well reproduced. Dr. MacKenna deserves great credit for having provided the profession with a clear exposition of modern dermatological teaching, and his book should prove very popular.

DENTAL RADIOLOGY.

By Christopher Kempster, M.R.C.S., L.R.C.P. Lond., Medical Officer in Charge, X Ray Department, Hampstead General and North-West London Hospital and Manor House Hospital, Golders Green. London: The Scientific Press, Ltd. 1922. Pp. 184. 10*s.* 6*d.*

This little book is of handy size and contains much useful information; it is not, however, very well balanced, and might well have been written with rather more care. The 19 pages devoted to description of X ray apparatus, including five from Codd's "Induction Coil Design," which form the first chapter, seem to us excessive in a work on dental radiology. It is stated that a dental radiologist would require an apparatus capable of giving 10 or 15 milliampères for 8 or 10 seconds. As dentists invariably use films, such an exposure appears to be quite unnecessarily long. It is also stated that the Rhumkorff coil is a "step up transformer," but this is hardly correct. The term "transformer" should only be used when referring to alternating current. The author states that there are two kinds of interrupters in general use, the mercury and electrolytic, but under the heading of the former only one kind is described, that of a jet brake, and only one form thereof, the Sanax type. He concludes this chapter with the opinion that an interrupterless transformer and Coolidge tube is the best combination for X ray work. Several makes of this type are on the market and appear to be satisfactory.

The second chapter, on X ray tubes, should prove useful to beginners in dental radiology. With the statement that tubes should be selected for the particular work to be done we cordially agree, also with Dr. Kempster's experience that tubes all vary and that each has a normal current at which it will work best. This point, which refers to "gas tubes," is well worth noting. The technique of film radiography described in Chapter III. will strike many as slow and cumbersome, and unsuited for work on children. Illustrations of positions for extra-oral radiography with large plates are given, showing the patient merely resting the face against the plate cassette, without any means whatever for steadying the head. This method may succeed in a few cases, but it is likely to fail in the large majority. Again, the method shown for radiographing the maxillary antrums, where the patient merely balances the head on the plate cassette by the nose and chin, does not appeal to us as practicable. Chapter IV. deals with the development and fixing of the X ray film or plate. Dr. Kempster devotes 80 pages to the fifth chapter, entitled Interpretation of Dental Radiographs. Unfortunately this chapter is mainly filled with general matter on the uses and advantages of X rays not relevant to interpretation of results. The illustrations of the film radiographs are, on the whole, well reproduced; no extra-oral radiographs are shown. Chapter VI. is devoted to stereoscopy and localisation; with the remarks on the value of extra-oral stereoscopy we entirely agree. As to the dangers of X rays, discussed in a final chapter, the author states that there is no fear of ill-effect on the dental patient; disasters are certainly rare, but it must be admitted that in a very small percentage of cases, perhaps 1 in 10,000, damage may occur if no protective measures are adopted.

A readable and useful little book; we have indicated the places where in a future edition reservations or alterations would be advisable.

CURE OF THE DEAF BY ELECTRO-AERATION.

By J. L. Aymard, M.R.C.S., L.R.C.P. Lond., late Aural Specialist, Queen's Hospital, Sidcup. Johannesburg: Argus Printing and Publishing Co. 1922. Pp. 71.

This pamphlet, in spite of the confusion caused by excessive vituperation of the generally recognised methods of treatment, contains a sufficient description of Mr. Aymard's method to enable other workers to try it; to this end a chapter by Major Pelling on electrolysis from its physical aspect is helpful. The principal form of treatment on which Mr. Aymard bases his claims, and which he calls "electro-aeration," is electrolysis of the nasal passages and nasopharynx by means of a platinum electrode embedded in a tampon of cotton-wool saturated with a solution of common salt and magnesium sulphate, 5 gr. of each to the ounce of water; this is attached to the positive pole of the current, the negative electrode is placed in one hand, and a current of 5 milliampères is passed for 20 minutes or longer; his routine is three treatments a week as long as necessary. The tampon containing a platinum wire is passed along the inferior turbinal of each nostril, and packed well into the nasopharynx, and it is important that the plugs shall meet behind the septum. The beneficial effect is presumably due to the nascent oxygen evolved at the anode. Mr. Aymard appears to claim that inflammatory conditions of the nasal sinuses are curable by this means, but it is difficult to believe that inflammation within, say, the frontal sinus can be influenced by the action of an electrode lying along the floor of the nose; for the successful electrolysis of the sinuses it has so far been considered necessary to place the electrode within the affected cavity. Supplementary methods include electrolysis of the ear with the positive electrode in the auditory meatus, the high-frequency current, and zinc ionisation in aural suppuration; at the same time Mr. Aymard makes a point of removing tonsils and adenoids, and of resecting deflections of the septum; some of his results may indeed be due to these measures. Mr. Aymard states that he has seen, not a few, but hundreds of cases quite erroneously diagnosed as nerve-deafness and otosclerosis; and he holds the unusual view that aural polypi are an advantage in chronic suppuration in that they facilitate drainage. He does not make use of the tuning-fork in the examination of his patients. There is no doubt that the treatment of some cases of chronic catarrh and catarrhal deafness is in an unsatisfactory position, and that a method of treatment which proved to be more successful would be warmly welcomed.

L'Orthopédie en Clientèle.

Par J. Privat. Paris: A. Maloine et Fils. 1923. With 595 figures in the text. Pp. 817. Fr.25.

This book is intended to enable the general practitioner to diagnose and treat the usual orthopædic lesions on conservative lines. The use of plaster-of-Paris as employed by Dr. Calot, of Berck-sur-Mer, plays an important part in the work, and little is said of other kinds of appliances or methods of treatment. Operations, except aspirations and injections of abscesses, are barely referred to. As was to be expected of a surgeon who has studied in the Marine Hospital of Berck, surgical tuberculosis bulks largely in this volume, and the directions given are adequate to enable the practitioner to carry out the open-air treatment with which Alton, Oswestry, and other hospitals have familiarised us. We doubt, however, whether as good results can be expected in private practice as in a special open-air hospital, and the general practitioner who has the interests of his patients at heart will try and obtain admission for them to such an institution.

The section on deformities due to causes other than tuberculous are less authoritative and less practical, with the sole exception of the notes on congenital dislocation of the hip. Here Dr. Privat makes a timely claim of priority for Pravaz, of Lyons, who in the middle of the nineteenth century cured a number of cases of this affection by manipulative methods which resemble those successfully used at the present time, although he had not the advantage of using plaster-of-Paris. Having in mind the fact that this book has no pretence to be a complete handbook of orthopædic surgery, and ignores certain departments of the specialty, we can recommend it as a useful guide to practical treatment, and especially to the technique of plaster-of-Paris appliances. It is profusely and well illustrated.

Galen on the Natural Faculties.

The Loeb Classical Library. With an English translation by Arthur John Brock, M.D. Edin. London: William Heinemann. Pp. 339. 10s.

Although this book is dated 1916, we have only just received it, so that any delay in the review is not to be laid at our door. The admirable publications of the Loeb Classical Library are, or should be, known to every one who cares for learning, and this volume is of especial interest to the medical profession. Galen ranked second only to Hippocrates in ancient medicine, although all through the Middle Ages Galen's fame far outshone that of his acknowledged master. The treatise now before us forms, to use Dr. Brock's words in his introduction, "an excellent prelude to the study of his larger and more specialised works." It deals mainly with physiology in the modern sense, together with a certain amount of physics. The term *Physis* is used by Galen to express the power which governs the living organism, and it is the province of physiology to deal with the faculties of this power. The living organism is one, a unity, and all its parts "can only be understood and dealt with in relation to this principle of unity." Hippocrates, of course, had maintained this principle, and so had Plato, who says in his dialogue Charmides, quoting a Thracian physician, that "the part can never be well unless the whole is well."

Much of the treatise "On the Natural Faculties" is taken up with exposing and confuting the errors of Asclepiades and Erasistratus, and in so doing Galen shows a wonderfully accurate knowledge of physiology for his time. He knew that the arteries, or some of them, contained blood, and was also aware of the anastomoses between the arteries and the veins. He also knew that the blood got from the right side of the heart to the left, but he accounted for this by imagining a communication through the septum from one ventricle to the other. Dr. Brock gives us a short account of Galen's life, but we think that on p. 18 he is hardly fair in his statement about his conduct when Marcus Aurelius asked him to go to the front with him in the Marcomannic campaign. Galen certainly did refuse to go to the fighting front, but he did go to Aquileia where the troops mobilised, and worked there for some time trying to combat the ravages of the plague. He went in the year 168 and returned to Rome in 170 to look after the youthful Commodus, who had been entrusted to his care by the Emperor. As events turned out, it would have been better for the Roman world and for the credit of humanity in general if the plague had carried off Commodus, but that he turned out the baleful creature he eventually became was not the fault of Galen.

The medical profession owes a debt of gratitude to the editors of the Loeb Classical Library for having given to it in English such a valuable example of Galen's works. If they should choose to give us another of his treatises we would suggest the selection of either the "De Usu Partium" or the "Methodus Medendi."

JOURNALS.

Annales d'Hygiène.—A new series of the *Annales d'hygiène publique et de médecine légale* begins in the issue of January of the present year under the title of *Annales d'hygiène publique, industrielle et sociale*, which will be welcomed by all hygienists who have looked to the *Annales d'hygiène* for light and leading in the past. Its history dates back to the year 1829, and during the long period of its history the journal, under the editorship of Brouardel and Thoinot, has represented all that is best in French hygiene. A division of forces has now become necessary, and in future the *Annales de médecine légale* will appear separately under the direction of MM. Bathagard and Martin. The first number of the new series opens with an excellent paper on social hygiene by M. Eugene Montet; in this article are summarised some of the chief efforts now being made for improving French social conditions. The struggle against alcoholism is steadily gaining force in France. The efforts of the late Dr. Jacques Bertillon and others are beginning to bear fruit against this "chief of social diseases"; in a striking extract from M. Jean Finot's work "Sa Majesté l'alcool" some of the chief results of alcoholic excess in France are summarised. The rôle of social hygiene is not merely to diminish the ravages of social diseases, such as syphilis and alcoholism, but also to raise the standard of individual efficiency, and in this connexion M. Montet describes a noteworthy attempt to secure periodical medical examinations, on lines similar to those which have been popularised in the United States.

Tropical Diseases Bulletin. Vol. XX. No. 2. February, 1923.—The February number of the Bulletin contains the second part of a review of medical helminthology by R. T. Leiper. Kala-azar is reviewed in a series of 38 references by C. M. Wenyon, amœbiasis and dysentery (51 papers) by P. H. Manson-Bahr. C. M. Wenyon again reviews relapsing fever, yellow fever, and other spirochætoses, and Leonard Rogers the most important recent papers on leprosy. There are the usual book reviews and notices.

THE LANCET.

LONDON: SATURDAY, MARCH 10, 1923.

DISEASE AS AN ACCIDENT OF EMPLOYMENT.

THOUGH medicine and law do not always see eye to eye, each has occasional opportunities to watch the other's operations with a certain respectful and sympathetic curiosity. Medicine has one such opportunity in an illuminating article in the current *Law Quarterly Review* wherein is revealed the law's attitude to disease in relation to workmen's compensation. As is well known, Parliament in 1906 made special provision for compensating sufferers from certain scheduled diseases such as lead, mercury, or phosphorus poisoning, to which list the Home Office has added miners' nystagmus, writers' cramp, twisters' cramp, and other ailments. But the original and principal Workmen's Compensation Act of 1897 was silent as to disease. The free insurance which it offered to the British workman was in respect of "personal injury by accident arising out of and in the course of the employment." Parliament had tried to use clear and simple words, but it thereby imposed upon the law courts the task of saying how much those words would cover. All diseases may be personal injuries, but is a disease an accident?

Judges interpreted accident as "injury by some fortuitous and external event"; some element of bad luck and unexpectedness had, it seemed, to be present. It was easy enough to decide that the rupture of muscles or organs through over-exertion is an accident. But when the workman began to claim compensation for disease, it was hard to see how far such claims might go. The first big battle was fought over a wool-sorter who contracted anthrax. This was held to be an accident because the "accidental alighting of a bacillus" in the man's eye was comparable to the squirting of molten metal or of some poisonous liquid. It was, said Lord MACNAGHTEN, an accident that the noxious bacillus happened to be in that particular bit of wool, an accident that it was carried upwards instead of downwards, an accident that it struck the worker in a vulnerable spot and thereby entered his system. It was, in fact, a chapter of accidents. Then came a fresh conundrum. A miner, owing to the breakdown of a pump, had to stand in icy cold water and caught his death of pneumonia. This was held a proper case for compensation. "Extreme and exceptional exposure to cold and damp" amounted to accident. At the other extreme a stoker on the *Majestic*, who died of heatstroke two hours after exposure to great heat, was held to come within the Act. But, for fear the riddle should seem too easy, the law declined to give the same remedy to another stoker who, being stronger, took longer to kill. In the latter case the man was employed in the stokehold in the Red Sea and suffered for several days before he died instead of merely two hours. The legal distinction lay in the idea that extreme heat is a normal and well-known risk of the Red Sea and therefore not an accident. The same reason was fatal to the claim of a workman who was alleged to have contracted enteritis by inhaling sewer-gas. It was argued on his behalf that it was an accident that the poison bacillus happened to attack him, but the court said sewer-gas was not unexpected in a sewer, and so the claim failed. In a similar case a gardener was ordered to open up a cesspool. He died of disease asserted to have been contracted in that operation, but his widow failed because she could not show how he was infected. A fever hospital attendant who caught scarlet fever was equally unlucky in being unable to prove to the court's satisfaction the origin of his illness. Claims arising from paralysis due to lead poisoning and claims due to "beat hand" and "beat knee" have also failed under the 1897 Act, though such cases can come within the Act of 1906. These afflictions, being the consequence of a slow and gradual process, are not to be described as accidents. Angina pectoris and apoplexy claims have failed because, though the attacks came on during employment, there was no proof of accident—no evidence of exceptional strain at a given moment. Not to prolong the catalogue, there is, lastly, the case of a Scottish workman who, working amongst artificial manures, contracted blood poisoning by the infection of a scratch on his leg. Here the judges differed acutely. The Court of Session said his claim must fail because the time and circumstances of the "accident" (the scratch and the infection) were obscure. The House of Lords reversed this decision, saying that it was enough if the infection resulted from contact at some moment during the course of the employment.

Is it unreasonable to suggest that these legal subtleties and this incessant litigation are a sad waste of time and money? Casuistical and not always very scientific observation about the "alighting of a bacillus" at one time or another are cold comfort to a workman's widow. Mr. MARCUS DODS, the learned author of the article from which we have quoted, declares frankly that the Act of 1897 has broken down and ought to be replaced by a totally new scheme of general health insurance. The same opinion is held by others and especially by the political representatives of the workman who want to see his compensation more generously granted. Mr. J. L. COHEN, in a useful little book on Workmen's Compensation in Great Britain,[1] seems to favour a brand-new centralised, compulsory, non-contributory scheme of State insurance embracing all persons earning less than £350 a year. The advocates of such a scheme are impressed by the large working costs of the insurance companies to whom the employers at present have recourse. It is stated that the employer has to pay £8 for every £3 given in compensation to workmen. If it is shown that the administrative expenses of these companies working in competition are 30 or 40 per cent. while the expenses of a State insurance monopoly would not be more than 5 or 10 per cent., it is naturally argued that the State system would save large sums of which the workman might have the benefit. Mr. COHEN puts the total cost to the country of accidents and industrial diseases at from 36 to 48 million pounds a year—a colossal if somewhat elastic figure. If, with the aid of such influences as the "safety first" movement, industry can lessen its rate of accidents, if medical science can cope with industrial diseases and with the more abstract problems of fatigue, lighting, heat, and ventilation, if the law can be simplified and generalised so as to save the immense sums now spent on litigation, and if insurance can be cheapened, there should be sufficient margin to finance a system of workmen's compensation which would be something better than a legal gamble and which would cover every kind of accident or disease. The Chancellor of the Exchequer pointed out recently that an "all-in" method of insurance would present enormous difficulties, administrative, political, and economic. Nevertheless, Great Britain may some day decide to unify and coördinate the whole of its social insurance, health insurance, unemployment insurance, workmen's compensation, employers' liability, old age pensions and all. When that day comes, the medical profession must be ready to take its part in the framing of the scheme as well as in the operation of the machinery.

DIRECT INFECTION IN ENCEPHALITIS LETHARGICA.

The account of an outbreak of encephalitis lethargica in a school at Radway, Warwickshire, which we published in a recent issue,[1] is worthy of close study by those who may be called upon to diagnose this disease. Dr. L. L. Fyfe has chronicled many interesting and important details concerning the symptomatology and clinical course of the disease as manifested in this instance by young children. The events at this small school, however, are significant in a wider sense, for they shed further light on the natural history of encephalitis lethargica and help to make more clear the infectious nature of this epidemic disease. As formerly, with acute poliomyelitis and cerebro-spinal fever, so now with encephalitis lethargica, the personal incidence of the disease seems at first sight to be a matter of mere caprice on the part of the virus, and well-marked cases of the malady crop up in apparently sporadic fashion throughout the country. There still remains a strong impression that, even when the disease is comparatively prevalent and widespread, the individual cases occur as discrete and unconnected events. In 1921 MacNalty[2] recounted instances where multiple cases of infection had occurred, and later further instances of case-grouping were brought to light in this and other countries. In a severe wave of encephalitis lethargica that ingulfed certain villages in Lapland during February, 1921, the morbidity rate[3] was unprecedented and varied from 7·1 to 45·0 per cent.; whole families were involved, and side by side with acute typical cases were others in which the disease showed itself in various degrees of comparative mildness.

In this country the "Derby outbreak" of August, 1919, investigated and described by MacNalty,[4] in addition to demonstrating the infectious potentialities of the disease, provided the occasion for establishing on bacteriological grounds some new facts concerning the virus itself. It will be recalled that this explosive outbreak occurred in a home for girls, and out of a total community of 22 persons 12 individuals were attacked within a fortnight. The first two cases were probably infected from a common source—latent in the home itself or encountered outside—but it is likely that direct contagion accounted for the majority of cases. As an instance of infection clinically affecting many members of an institution the experience at Derby remained unique until the occurrence of the small outbreak recorded by Dr. Fyfe; at Derby the disease, with dramatic abruptness, fell upon a secluded community of young women (the majority of whom belonged to the most vulnerable age-period), quickly involved over half of the inmates, and caused the death of five of those affected. Of the 32 scholars at Radway a smaller proportion were infected; the invasion of the disease was insidious and for some time unrecognised by reason of the comparatively long interval between the first and subsequent cases and of the relative mildness of the clinical symptoms. The school had but lately reassembled after the summer holidays when, on Sept. 15th, one of the older girls was found to be fast asleep at her desk; with some difficulty she was roused sufficiently to be sent home, where she remained for a long week-end and then resumed her regular attendance at school although subject to daily bouts of somnolence and headache. On Oct. 9th the senior girl in the school, who occupied a seat immediately in front of the first patient, was overcome in a similar way, and on the 11th and 13th respectively two more girls were attacked. Alone among her school-mates, the first girl had spent part of the previous holidays away from the village; it would seem likely that she acquired her infection while on a visit to a neighbouring large city, and that the last three children to be affected derived their infection either directly or in a mediate manner from her. This would mean an average incubation period of 23 days. On the other hand, if the second case passed on the infection to one or both of the others the incubation periods would be considerably shorter and more in accord with events in the Derby outbreak. At any rate, it is difficult to avoid the conclusion that personal contagion was the method of spread here as it probably was in an instance reported by Reece,[5] where a nurse contracted the disease while attending a patient who was suffering from encephalitis lethargica and with whom she had not previously been in contact. Moreover, the instances of encephalitis lethargica in babies, born while their mothers were suffering from the disease (four such instances have been recorded in this country), surely must dispel any doubt as to the contagiousness of the malady.

Investigation failed to discover any obvious focus of infection with which the first patient at Radway school had come in contact during her holiday visits; but, it is noteworthy that, in at least three instances, where there was a familial grouping of cases in isolated districts, the first patient to be attacked had recently been visiting a populous centre. Again, the comparative frequency with which the more striking examples of multiple infection are referable to isolated districts or secluded communities is one of the most significant features in the epidemiology of encephalitis lethargica. It would almost seem as if the dwellers in populous centres had, through constant contact with infection, acquired an immunity to the virus which has not been possible for smaller communities living in comparative seclusion. When, however, a susceptible member of such a community mixes with the world at large he may acquire the virus and on returning infect one or more susceptible persons in his home or place of work. The researches of Levaditi, Harvier, and Nicolau, indeed, appear to show (as suspected for some time on clinical and epidemiological grounds) that the virus of encephalitis lethargica is widespread and exists in more than one form; it is perhaps sufficient for the clinician and the epidemiologist to know that there are "carriers" who harbour the virus in virulent form and that, in an attenuated degree, the poison lurks in the saliva of healthy individuals. Another lesson may well be learned from the little outbreak. It is the custom in many a medical inquiry to search for clues among the denser areas of population, to use the weight of mass statistics, and to avail ourselves of the technical facilities and professional experience which are to be found in all important centres. But in the case of encephalitis lethargica, and some kindred diseases, a more fruitful field for inquiry will often be found in the less populous districts where the threads of an inquiry can be more easily caught up and the knots more quickly unravelled. Not in cities, nor in hospitals, then, but in such quiet rural retreats as Radway village may be found the solution to some of our epidemiological problems, and in such quests the country practitioner, the village schoolmistress, and the health visitor can render invaluable public service. Indeed, they have done so.

ADVANCES IN CANCER RESEARCH.

EXPERIMENTAL cancer research is at the present moment perhaps one of the most active departments of medicine. The two last volumes of the Proceedings of the Japanese Pathological Society[1] contain out of less than 200 papers over 30 papers on experimental cancer research. Last year an informal international meeting of a number of leading investigators in experimental cancer research was held in Amsterdam under the presidency of Prof. ROTGANS, of Amsterdam, which led to the formation of the Leeuwenhoek Vereeniging, a society for the study of malignant tumours. The first meeting, which was held without ostentatious publicity last October, dealt exclusively with the subject of tar cancer. The Proceedings[2] now published as an unpretentious volume of 53 pages, represent one of the most important publications which have as yet appeared on the subject of cancer, since it summarises investigations which are proceeding in the different leading laboratories. Owing to the distance, Prof. YAMAGIWA, of Tokio, and Dr. W. H. WOGLOM, of New York, who had been invited, were prevented from being present and reporting on their investigations. The slim volume contains contributions by Prof. J. FIBIGER, of Copenhagen, the father of this line of cancer research, and his assistant, F. BANG; by Dr. H. T. DEELMAN and Dr. WATERMAN, of Amsterdam; Dr. J. A. MURRAY and Dr. A. LEITCH, of London; G. ROUSSY, R. LEROUX, and ED. PEYRE, of Paris; B. LIPSCHUTZ, of Vienna; R. BIERICH, of Hamburg; BR. BLOCH, of Zurich; and A. TEUTSCHLANDER, of Heidelberg.

In reading through these reports one cannot help being struck by the significant advance which has taken place during the last four years in our knowledge of the ætiology of cancer. The same impression is gained from reading a recent paper by Prof. FIBIGER,[3] which gives an admirable summary of the recent work on the experimental production of cancer. Some of the most fundamental problems, the solution of which has defied the efforts of clinicians and morbid histologists for half a century, yielded their secrets as soon as the experimental method could be applied. In fact, it may be doubted whether the problem of the ætiology of cancer could ever have been solved if the clinical study of the disease in man had been our only mode of attack, for the experiments with tar have shown that a tumour may develop long after the irritant ceased to act. From this discovery of a long "period of latency" which in man may extend over years, a number of important conclusions follow. Thus cells may have acquired the tendency to develop later malignant properties before there is an external indication of this change in their morphological appearances. Again, the characteristic age-incidence of cancer is not due to the fact that the cells of old animals are more prone to cancerous degeneration than the cells of young animals. Experiment shows that they are not; the correct explanation is that the irritant must act over a considerable period, to which has to be added the period of latency. There is further the important demonstration that tumours which are apparently benign may develop into malignant new growths, and that a trauma which by itself is incapable of producing cancer will greatly accelerate the development of cancer following upon the application of a suitable irritant. This last fact throws light on the occurrence in man of malignant new growths after a trauma and at the site of the trauma. If there is a causal relationship it is probably that the trauma shortened the period of latency. Attempts to immunise mice against the development of cancer have so far failed. The methods which will produce a resistance against the homologous transplantation of tumours do not confer resistance against the development of cancer any more than they confer resistance against the autologous transplantation of tumours. Lastly, there is the significant fact that mice which have once developed a cancer after the application of tar, and have been cured by operation, do not react to the subsequent application of tar by the development of a second cancer. This fact explains the comparative rarity of the occurrence of multiple tumours in man, and may lead to other important developments. At present there is at any rate some consolation in the reflection that, probably, we can have cancer but once.

We have only indicated here some of the definitely ascertained results concerning the ætiology of cancer which have been obtained. But it is clear that since malignant disease can be produced experimentally therapeutic and prophylactic measures can now be placed on a controlled experimental basis. The work is necessarily slow and requires a good deal of patience. It takes months in a mouse, and over a year in a rabbit, even to produce a new growth, and the mortality is high. This may account for the curious lack of appreciation of the significance of this work outside the narrow circle of those who are engaged on it, and for the failure of the wider medical public to realise that, so far as cancer research is concerned, we live in stirring times.

PUBLIC HEALTH QUESTIONS IN BELFAST.—The Belfast City Council is promoting a Bill in the Parliament of Northern Ireland to secure wider powers for dealing with the food-supply of the city. To consider these proposals a joint meeting of the Ulster Medical Society and the Ulster Branch of the British Medical Association was held in the Medical Institute, Belfast, on March 1st, with Prof. J. A. Lindsay in the chair. A resolution, proposed by Dr. D. Gray, seconded by Dr. J. S. Morrow, and supported by various members, was passed unanimously: "That every public health authority should have the right to examine and inspect the source of supply of any article of food offered for sale or consumed within its area."

Annotations.

"Ne quid nimis."

THE OPIUM CONVENTION AND THE LEAGUE OF NATIONS.

The progress made by the League of Nations in putting into effective operation the International Opium Convention, which was signed at the Hague 11 years ago, has not been rapid. The objective of the Convention was "to bring about the gradual suppression of the abuse of opium, morphine, and cocaine, as also of the drugs prepared or derived from these substances, which give rise or might give rise to similar abuses." To bring about coöperation to this end by more than 50 Powers, some of which are not yet included within the League of Nations, is necessarily a complicated task, and demands both time and patience. It is satisfactory to learn that the United States of America and Germany, although standing outside the League, are lending assistance and advice in this humanitarian work. It is, moreover, rumoured that Turkey is "favourably considering adhesion to the Opium Convention," and Persia, which made serious reservations on signing the treaty, is now likely to ratify *sans phrase*. As these two latter countries are large producers of opium, their loyal coöperation should be particularly welcome.

We understand that the question as to what constitutes the "legitimate" use of opium and of the other drugs has been engaging the attention of the Advisory Committee of the League, and that a joint subcommittee formed from the Health and Opium Committees has expressed the opinion that "medical use should be considered the only legitimate use of opium and other dangerous drugs," and that "in the opinion of the doctors, the use of opium as a stimulant could not be considered legitimate even in tropical countries." These opinions appear to be in conflict with the views still held by the India Office, which, in a recent publication entitled "The Truth about Indian Opium," reiterated as "unchallenged" the findings of the Royal Commission of 1895 to the effect that opium was to be regarded as a valuable domestic medicine, as useful in fever and prophylactic against malaria, as a stimulant for the purpose of "resisting fatigue," and even as a "specific against old age." The Royal Commission of 1895 reported that "opium is used as a stimulant, and it is also largely consumed in India for the mitigation of suffering and the prevention or cure of disease. It is the universal household remedy. It is extensively administered to infants, and the practice does not appear to any appreciable extent injurious." The Commission did not condemn the export of Indian opium to China and elsewhere; moreover, they found that "in the present circumstances the revenue derived from opium is indispensable for carrying on with efficiency the Government of India."

It is to say the least doubtful whether the findings of the Commission of 1895 can be maintained to-day. In 1906 the House of Commons with unanimity condemned the Indo-Chinese opium trade as "morally indefensible," and in 1917 it was brought to an end. Lord Morley, when Secretary of State for India, declared that the Commission of 1895 had "somehow or other failed to satisfy public opinion." The Shanghai Commission of 1909, and the three Hague Conferences of 1911–12, 1913, and 1914, have served to show the world-wide abuse of these "drugs of addiction," and the need not only for national but for international legislative and administrative control to limit their production and distribution to medical and legitimate purposes. Medical opinion generally will probably now be found to range itself alongside the advice given to the League of Nations to the effect that the only legitimate use is the medical use, and to doubt the virtues, even in tropical countries, ascribed to opium by the Commissioners of 1895. Meanwhile we learn from a recent answer in the House of Commons[1] that in the year 1920, 322,464 oz. of British-made morphia were exported from this country, or about nine tons, to which must be added exports by parcel post and exports of preparations containing morphia. The contention that much of this exported morphia is used for illicit purposes will probably be unchallenged.

CENSUS FIGURES FOR LONDON.

The appearance of Vol. II. of the Census tables (1921) for the County of London is welcome, for there has been over-much delay in issuing these two first of the English Census volumes. There is no explanatory statement of the main inferences from the tables, which will appear in a later volume, and the searcher after truth must therefore laboriously work out his own conclusions. But even so, the statistician can find much of interest in the masses of figures. Thus we learn that of the total population of London, nearly 20 per cent. are under 12 years of age; and that of the total population over 13 per cent. are unoccupied, including retired persons. The largest single-grouped industry is that of transport workers, who numbered 253,000, next to this come commercial and financial workers, of whom there are over 163,000, while metal-workers, numbering over 115,000, come third, and clerks, over 102,000, fourth. The predominance of the financial and mercantile industries of London over manufactures is well shown in these figures. The limited extent to which the population of London is foreign-born is shown by the fact that fewer than 146,000 of its 4½ millions were returned as born in foreign countries, fewer than 42,000 as born in Greater Britain, while in over 30,000 the birth-place was not stated. Nor is the Scottish contingent so large as it is commonly thought to be, for of the total population of London 4,129,934 were born in England and only 49,881 in Scotland. Perhaps the most interesting table in this report is that dealing with dependency, and it is the only table in the volume in which ratios are stated. Among the total number of married men who were enumerated in London in 1921, the average number of living children under 16 years of age per family was 1·26, the highest proportion (2·04) being among families with fathers aged 35–45. This table sheds some light on the subject of net fertility. The number of children per family of younger parents doubtless represent uncompleted families, and the figures in this table need to be supplemented by those given in the Registrar-General's Fertility Report.

THE EVOLUTION OF SANATORIUM TREATMENT.

Two recent reports from widely separated centres afford instructive evidence of the direction in which modern sanatorium treatment is evolving. In the annual report for 1921 of the medical officer of health for Newcastle-upon-Tyne, there is a paper by Dr. C. G. R. Goodwin, medical superintendent of Barrasford Sanatorium. He has come to the conclusion that dispensing with the old austerities of open-air treatment and the discomfort and even misery it provokes in the winter, does not impair the results. Fresh air is a necessity, but bitterly cold air is undesirable and even harmful. With regard to weight, he does not attempt to increase it above the patient's normal weight in health, for excessive fat is promptly lost on discharge, with depressing effects on the patient who imagines he is immediately losing ground. "Rest is by far the most important measure in the treatment of active pulmonary tuberculosis . . . . when it is certain that they are free from fever, they are sent morning and afternoon on walks . . . . When a patient has been on full exercise for a few weeks with general improvement, he is offered a little light work as an alternative to the morning walk. This is to be regarded as a means of varying the monotony rather than as an attempt at real work . . . . the basis of treatment is rest, and hard work has no place in this sanatorium's routine, however carefully it might be graduated." In a paper with the heading "The Effect of Six Weeks' Bed Rest Upon Patients Entering Trudeau's Sanatorium," Dr. Lawrason Brown and Dr. Fred H. Heise [1] give an account of their "rest squad." Thinking that intensive bed rest for six weeks might benefit all cases of pulmonary tuberculosis at the onset of treatment, regardless of symptoms, they set aside two cottages for this experiment. Meals were served at the cottages, and the patients were allowed to eat at a common table in their bath robes. At the end of the six weeks the patients were gradually introduced to the ordinary sanatorium routine. The "rest squad" included 161 patients and 629 other patients who underwent the old sanatorium routine served as controls. The "rest" cases had, on the average, one month less treatment than the "no rest" cases. After publishing details, the authors conclude: "While no striking evidence is produced to show the benefit of six weeks' bed rest to cases entering the Trudeau Sanatorium, under the conditions existing relative to selection of cases and time of beginning treatment, the authors nevertheless feel that under more favourable conditions, especially when treatment can be begun immediately upon diagnosis, intensive bed rest will prove of benefit to the patient, although symptoms of definite activity are absent. Surely a much more impressive idea of the seriousness of the disease and of the necessity of proper care is inculcated, and this should, in later days, months, or years, show beneficial results in prevention of relapse."

---

[1] The Lancet, March 3rd, p. 468.

A PASTEUR EVENING AT THE ROYAL SOCIETY OF MEDICINE.

IN the medical world, at least, the relations of France and this country could not be more cordial than they are at present. Last year the Académie de Médecine celebrated the centenary of Jenner, and on Feb. 28th the Royal Society of Medicine devoted its social evening to the memory of Pasteur. Sir William Hale-White, the President of the Society, delivered an address on Pasteur in Relation to Medicine, a necessarily brief chronicle of the origin and family life, the incessant labours and brilliant and lasting achievements of this great master. As a schoolboy Pasteur showed no special talent except for drawing, and when in 1842 he was examined for a degree in science he passed without distinction. In the following year he secured admission to the École Normale at Paris and began his work in chemistry and particularly physical chemistry, for which alone he would have been famous. For many years his life was devoted to research in organic chemistry. From pure science he went by degrees to applied science, and for 20 years he worked at the problems of fermentation. Sir William Hale-White referred to Pasteur as the founder, with Koch, of modern bacteriology and with Lister of modern surgery. His work on silkworm disease resulted in the saving of one of France's greatest industries, whereas his service in the prevention of anthrax was another industrial boon. The steps which led to Pasteur's investigations on rabies were also detailed by Sir William Hale-White, while his discoveries in physical chemistry, and notably his work on tartaric acid, formed the subject of an address by Prof. Lowry. Prof. Lowry described how Pasteur was able to pick out the "left-handed" crystals of the optically inactive sodium ammonium racemate from the "right-handed" crystals and by re-dissolving them to make two solutions, one of which rotated polarised light to the left while the other rotated it to the right. The "right-handed" salt occurred in nature and could be fermented by a certain yeast, whereas the "left-handed" salt was unaffected by this or any other organism. The two sets of crystals were related as object and image. Many other organic substances existed in these two forms, but our digestive apparatus was capable of dealing only with the "right-handed" variety. Here, Prof. Lowry said, might have been the real tragedy of Alice when she entered the regions beyond the looking-glass, where she would inevitably have starved in spite of abundance of food. An illustrated lecture on Pasteur as an Artist, by Dr. Gustave Monod, of Vichy, who presented to the Society a book of reproductions of Pasteur's drawings, brought this interesting function to a close. The pastel drawings made by Pasteur as a youth were said to show evidence of considerable ability as well as keen observation of detail.

SEPTIC MENINGITIS OF AURAL ORIGIN.

UNTIL a few years ago septic meningitis was regarded as a necessarily fatal complication when occurring in the course of aural suppuration, but recently recoveries have been reported in slowly increasing numbers; and, though these recoveries still form but a very small proportion of the whole, yet the problems involved are now being attacked in a more hopeful spirit. The technique of operative treatment and the methods of early diagnosis are chief among the problems whose elucidation will further lower mortality. There is little doubt that early operation, while the meningitis is still localised, offers the only reasonable prospect of success, and that recovery is very exceptional when a case has reached the stage in which micro-organisms are present in the cerebro-spinal fluid. Mr. G. J. Jenkins raised these questions in a paper read before the Tenth International Congress of Otology[1] last July. He stated that it remained for otologists to recognise and determine: (1) Those septic affections of the ear that are especially prone to cause meningitis; (2) those symptoms and signs that are associated with the early stages of meningitis; and (3) those symptoms and signs that will indicate the region of greatest intensity of the inflammation, as well as the probable limits, if any, of the affected area. Thus he believes that the principal factors influencing changes in the cerebro-spinal fluid obtained by lumbar puncture are the site of maximum infection and the stage reached by the inflammatory process, and that the nature of the invading organism has relatively little influence. He endeavours to distinguish clinically between primary infection of the cisterna pontis, which can only occur through the labyrinth, and primary invasion of the trabeculated subarachnoid tissue such as takes place through the tegmen into the middle fossa and from an infected lateral sinus into the posterior fossa. In the former the symptoms are largely masked by the concomitant labyrinthitis, but the cerebro-spinal fluid on lumbar puncture shows increase of pressure, turbidity, and numerous cells; the temperature is only raised to 100° or 101° F., and the pulse is slow, the patient torpid, while the rigidity of the neck muscles, which slowly develops, is a most important sign. In localised meningitis in the middle fossa, the temperature is usually 101° to 102°, with the pulse-rate increased in proportion, and the lumbar puncture fluid normal or very little altered; the only suggestive sign being well-defined pain, often with tenderness, above the ear. Lumbar puncture alone cannot be seriously regarded as a method of treatment; and besides eradicating the causative ear disease, drainage must speedily be established at the site of maximum infection. In all cases of acute labyrinthitis, or of acute inflammation of the ear with old destruction of the labyrinth, a lumbar puncture is done at the beginning of the operation, and the fluid examined during the performances of the radical mastoid; if the report indicates meningeal inflammation, trans-labyrinthine drainage through the internal auditory meatus is effected. In all cases of acute labyrinthitis a superior and inferior labyrinthotomy is done by Mr. Jenkins, although the cerebro-spinal fluid be normal; on this point he is at variance with the great body of otological opinion, for the majority hold that it is safer not to operate in the acute stage of labyrinthitis, unless signs of meningitis are present. In our present issue we print a report by Mr. H. L. Martyn of a case of recovery from otitic meningitis after drainage by a different route. Now that it is becoming recognised that recovery from otitic meningitis is possible, such cases will be treated with greater hopefulness and with correspondingly greater success, and the publication of the successful cases assists in the progress of treatment by encouraging others to obtain similar results.

MEDICINE IN FORMOSA.

The medical report of the Tainan Hospital in Formosa has reached us. Dr. J. L. Maxwell and Mr. Percy Cheal, reviving the practice suspended during the years of unsettlement, deal with the period from January, 1920, when the hospital was reopened, to the end of October last. The hospital, which is under the care of the English Presbyterian Mission, disposes of a large amount of clinical material: nearly 3700 operations were performed during this time; 4700 injections were given, a large proportion for the treatment of leprosy and syphilis, with some 1300 anti-cholera vaccinations; and there was a total of 77,000 out-patient attendances. The medical officers intend to publish yearly reports in the hope of directing renewed attention to the comparative pathology of different human races. The knowledge already obtained would, they think, sound the death knell of some current theories of the ætiology of disease. For example, the theory of the bovine origin of certain forms of tuberculosis might have been promulgated with more caution had it been known that tuberculosis in all forms is rampant among Chinese whose diet precludes any possibility of bovine infection. Again, they note as a hardy perennial in medical literature the theory that internal hæmorrhoids are due to the abandonment of the primitive posture in defæcation; whereas in the Tainan records the condition commonly occurs in the male sex which still adopts a primitive posture, while the women, who use commodes, are almost immune. Ankylostomiasis occupies the close attention of the hospital, the stools of all in-patients—over 2000 a year—being examined on admission, with the result that an infection rate of nearly 40 per cent. has been found. The Tainan medical officers recognise the drawbacks attending the exhibition of all the usual vermicides, and an experiment with carbon tetrachloride is now promising well. This drug, it may be noted in passing, has recently gained good opinions[1] in the Southern States of U.S.A. Prolonged trial has been given to the newer remedies for leprosy, and more than 3000 injections of chaulmoogra oil or its derivatives have been given to some 120 patients, of whom 25 per cent. have apparently been cured and others greatly improved. Tartrate of antimony has proved disappointing in the treatment of lung distomiasis, the number of eggs expectorated during the treatment not diminishing or showing signs of degeneration. On the other hand, intravenous antimony has proved of help in apparently hopeless cases of granuloma pudendi in which salvarsan has invariably failed. Cancrum oris is in Tainan a not infrequent sequel of measles, and whereas formerly almost hopeless, salvarsan injections are now saving the lives of 75 per cent. of the sufferers. Nevertheless, the success of this treatment raises a difficult ethical problem, inasmuch as the life prospect of a heathen girl with disfigured face is distressful. Massive splenomegaly attended with cirrhosis of the liver and terminal ascites is terribly common in Formosa and its treatment as yet unsatisfactory, although splenectomy at an early stage has been encouraging. The report concludes with the expression of a doubt whether work of such importance and on such a scale should be left to the charge of two doctors, two part-time trained nurses, two more or less trained Formosan assistants, and a few others devoid of any training whatever. The difficulty is one of finance.

HYPERSENSITIVENESS TO SILK.

An instructive case of hypersensitiveness to silk is the subject of a modest note by Dr. J. A. Clarke and Dr. G. P. Meyer in the Journal of the American Medical Association of Jan. 6th. A woman student, aged 21, with a typical family history of asthma, eczema, and hay-fever, was referred to the authors of the note for asthma of three months' duration. There were no clues as to a possible cause, and physical examination revealed nothing but chronic eczema. Tests according to Cooke's technique gave no results. Later, the patient, who had previously denied having had urticaria, volunteered the information that for the last two years only, following an attack of influenza, "welts" had developed on her skin whenever it came in contact with silk. She brought a silk blouse to the consulting room, and, having put it on in the presence of the authors, in 15 minutes developed a giant urticaria at all points of contact, but most markedly on the arms. Twelve minims of epinephrin gave little relief, and the urticaria lasted 12 hours though the blouse was at once removed. The silk was extracted according to the method of A. F. Coca, and an intradermal test gave rise to a typical constitutional reaction lasting two hours, with urticaria, asthma, &c. The extract from a single strand of silk gave a sharp cutaneous reaction. This hypersensitiveness is apparently rare—not one of 500 cases of asthma and urticaria tested reacted to the extract. Other attacks occurred, mostly in connexion with silk worn by companions or, in one instance, with a silk bed quilt. Hyposensitisation was attempted, but after four months of treatment the patient was able to stand barely half the original dose which had given an alarming reaction. There was a decided improvement noticeable in the asthma, which might be attributable to the injections or to the care with which the patient now avoided contact with silk. The authors conclude that there are cases in which hyposensitisation is effective to such a slight extent as to be almost valueless. However, as the authors themselves point out, the dosage for desensitisation is open to criticism. Though the amount of protein involved in the injections was extremely uncertain, yet the doses appear to be very big as compared, for example, with the well worked out cases of hay-fever and horse asthma. Again the doses were repeated once a week, or even at longer intervals than that. Desensitisation against horse asthma can be done much more expeditiously by inoculating every day. This case is interesting in that the routine skin reactions, though they gave some positive reactions, yet gave nothing of value. J. Freeman considers that unless the history of the patient gives a decided lead, as it did toward silk in this particular case, nothing is likely to come out of routine skin testing.

THE INNERVATION OF THE HUMAN PIA MATER.

Having regard to the views at present held by physiologists as to the conditions which determine the intracranial blood circulation, the summary of the innervation of the pia mater and the choroid plexus by Philipp Stöhr,[1] the distinguished histologist, is of considerable importance. Stöhr investigated the distribution of the pial nerves in human fœtuses, and in three adults who were executed. He found that all the blood-vessels of the pia mater and choroid plexus are supplied by nerves. The arteries are provided with a coarse network of fibres in the outer part of the tunica adventitia, and a finer network in the deeper part of this coat, while the muscular coat has very fine fibres. Sensory nerve-fibres are present and here and there ganglionic nerve-cells. The smallest arteries are especially rich in sensory nerve-endings, the capillaries also are accompanied by nerves which terminate in knob-like endings on the wall of the vessel. The small veins are also provided with nerves. The nerves to the blood-vessels arise partly from the carotid and vertebral plexuses, and partly from the third, sixth, tenth, eleventh, and twelfth cranial nerves, and other branches come from the sympathetic and parasympathetic. The sensory fibres to the arterioles come from the cranial nerves named. The nerves present in the connective tissue coat of the vessels of the pia come mostly from the third, sixth, ninth, tenth, eleventh, and twelfth cranial nerves or direct from the pons, and the nerves are most numerous and largest on the vessels at the base of the brain, while in the vertex they are fewer in number and smaller in diameter. The choroid plexus of the fourth ventricle receives fibres from the ninth and tenth cranial nerves. The several nerve-fibres interlace and form a wire-meshed network. Some of the fibres are processes of the nerve-cells which lie singly or in groups in the pia mater, and the network is distributed all over the pia of the cerebrum, but so far nerve-endings have not been found on the pia of the cerebellum. The blood-vessels of the choroid plexus receive an extraordinary rich supply of nerve-fibres, and some of them have characteristic nerve-endings—pear-shaped or like Meissner's corpuscles. The author concludes that the blood circulation in the cranium is under the control of the nervous system, and the prime function of the pia mater seems to be to regulate the amount and pressure of the blood supplied to the cerebral substance. The functions of the choroid plexus equally is also under the influence of the nervous system and one function of the plexus would seem to be to help to regulate the pressure of the cerebro-spinal fluid. The nerve-terminals in the pia act as protective organs for the control of intracranial pressure and perhaps also for the movements of the cerebro-spinal fluid. The third and fourth ventricles are protected by the rich nerve-plexuses in their blood-vessels.

POST-GRADUATE COURSES IN THE PROVINCES: THE UNIVERSITY OF BRISTOL.

IN connexion with the post-graduate courses arranged from time to time at local centres such as Trowbridge and Barnstaple, in the neighbourhood of Bristol, a classified list of demonstrations available for selection by local centres during 1923 has been issued. The courses arranged in the past two years[1] have been so much appreciated by practitioners in various districts in the south-west of England that the adoption of a similar scheme by other universities might afford some solution of the problem of providing post-graduate revision courses throughout the country. The syllabus of the courses available in the south-west of England is as follows :—

Circulatory System.—(1) Arterial tension ; (2) Newer methods of examination of cases of cardio-vascular disease ; (3) Principles of prognosis and treatment of heart disease ; (4) Ventricular failure—forms, signs, and treatment ; (5) Bradycardia, tachycardia, and fibrillation—causes, diagnosis, and treatment ; (6) Arterio-sclerosis.

Alimentary System.—(1) Physiology and pathology of alimentary tract ; (2) Diagnosis and treatment of gall-bladder diseases ; (3) Abdominal pain and its causes ; (4) Differentiation of the acute abdomen and its simulators ; (5) Diagnosis and treatment of common gastric disorders ; (6) Congenital hypertrophic pyloric stenosis ; (7) Peptic ulcers—true and false ; (8) Appendicitis and functional disease of the colon ; (9) Treatment of constipation ; (10) Practical value of routine examination of stools ; (11) Diagnosis of hepatic insufficiency ; (12) Medical diagnosis and treatment of dyspepsia.

Respiratory System.—(1) Pneumonia—complications and treatment ; (2) Blood and sputum in atypical lung conditions ; (3) Effects of thoracic lymph-gland infections upon subsequent lesions ; (4) Modern treatment of empyema and abscess of the lung.

Genito-Urinary System.—(1) Modern treatment of stricture and prostatic cases ; (2) Renal efficiency tests and their value in medical and surgical practice ; (3) *Bacillus coli* infections of the urinary tract ; (4) Toxæmia of pregnancy ; (5) Syphilis in women—diagnosis and treatment.

Nervous System.—(1) Mental deficiency and feeble-mindedness—ætiology, diagnosis, and treatment ; (2) Diseases of the extra-pyramidal motor tracts—ætiology, signs, prognosis ; (3) Paroxysmal paralysis of the elderly ; (4) Hysteria—signs, differential diagnosis, and treatment ; (5) Signs of mental breakdown ; (6) Value of cerebro-spinal fluid examinations ; (7) Recent work in neuro-syphilis—its bearing on treatment ; (8) Infantile paralysis—ætiology, stages, prevention of deformities.

Sensory Organs and General Diseases, &c.—(1) Tonsils and adenoids and treatment of otorrhœa ; (2) Nose, throat, and ear disease, considered as sources of general medical symptoms ; (3) Nasal catarrh—symptoms, ætiology, and treatment ; (4) Ear discharges—sources and treatment ; (5) Iritis, associated with chronic infections ; (6) Common forms of conjunctivitis with regard to age-periods and treatment ; (7) The reading of radiograms and the applications of radiology ; (8) Difficulties associated with the administration of anæsthetics ; (9) Inter-relations of internal secretion glands ; (10) Endocrinology ; (11) Treatment of painful feet ; (12) Diabetes and modern methods of treatment ; (13) Physio-therapy—principles and methods.

Pathology and Bacteriology.—(1) Normal and acquired resistance to disease ; (2) Pathology of breast cancer applied to treatment ; (3) Choice of pathological methods in diagnosis ; (4) Anaphylaxis and its applications in diagnosis and treatment.

Dental.—(1) Oral sepsis—extraction of teeth and necessary preliminaries ; (2) Points in the care and treatment of children's mouths.

A series of eight post-graduate demonstrations will be held in the medical school of the University at 3.30 P.M. on Thursdays, beginning on April 12th. Inquiries should be addressed to the Director, Post-Graduate Medical Studies, Pathological Department, University of Bristol.

THE DIAGNOSIS OF HILUM TUBERCULOSIS.

HILUM tuberculosis has been caustically defined by Sir James Kingston Fowler as " a shadow first seen in a darkened room and not yet clearly recognised in the daylight of the post-mortem room." Undoubtedly there is such a condition ; the work of Dr. Clive Riviere and numerous Continental investigators has established its existence beyond peradventure. But Sir J. Kingston Fowler has done good service in holding up to ridicule the radiologist who relies on a skiagram alone for the diagnosis of this condition. It is certainly elusive, and in a recent paper Dr. A. Brinchmann,[1] of the Rikshospital in Christiania, has shown that both the positive and the negative evidence of the X rays is unreliable. He selected 180 skiagrams, taken of the chests of 154 children, and while he was scrutinising these skiagrams he kept himself in ignorance of the clinical reports. The skiagrams showed signs of enlarged bronchial glands in 41 cases, and infiltration of the lungs in 12. The evidence was doubtful in 51 cases, and in 50 there was no definite sign of enlarged bronchial glands. Of the 41 children with skiagraphic evidence of enlarged bronchial glands, 10 showed no clinical sign of this condition. On the other hand, among the 50 children whose skiagrams were negative, there were as many as 28 with clinical evidence very suggestive of hilum tuberculosis. Dr. Brinchmann's comparative study of the seven most popular clinical tests for hilum tuberculosis leaves them with a reputation as tattered as that of the X rays. The seven tests were : (1) Dullness in the interscapular region, (2) dullness over and just beyond the manubrium sterni, (3) dullness over the spinous processes of the fifth and sixth vertebræ (de la Camp's vertebral percussion), (4) tenderness over the spinous processes of the second to the seventh dorsal vertebræ (Petruschsky's spinalgia), (5) Eustace Smith's sign, (6) a bronchial blowing sound in the interscapular region, and (7) d'Espine's sign. The 180 children subjected to all these tests were grouped in two classes according as the history and symptoms did or did not suggest the existence of hilum tuberculosis. There were 103 in the first class, 77 in the second. Eighty in the first class and 23 in the second reacted to tuberculin. d'Espine's sign was positive in 65 per cent. of the first class and in 12 per cent. of the second. Eustace Smith's sign was positive in 13 per cent. of the first class and in 4 per cent. of the second. Interscapular blowing respiration was heard in 42 per cent. of the first class and in 5 per cent. of the second. De la Camp's sign was positive in 18 per cent. of the first class, and in the second it was invariably absent. Dullness over the manubrium and in the interscapular region was also found far more frequently in the first than in the second class. But, and this was a very significant observation, there was not a single case in which all the seven signs or tests were positive. The signs which emerged from these investigations with least tarnished reputations were d'Espine's and interscapular blowing. At present it must be admitted that there is not a single test which is pathognomonic of hilum tuberculosis. It cannot, however, be denied that great and growing importance is attached to this manifestation of tuberculosis, and we would refer our readers to a recent short monograph on the subject by Dr. Marcel Paillet.[2]

INTERNATIONAL HEALTH ORGANISATION.

LAST week saw the beginning of a tour in Great Britain of a party of medical officers from 14 European countries, the United States of America, and Japan. The work was confined to London during the first week, and the tour is now being continued in various provincial centres in England and Scotland and will last until Eastertide. The delegates will conclude their visit with some further observations in London and a conference. The tour has been arranged by the Health Organisation of the League of Nations, with the financial facilities put at their disposal by the Rockefeller Foundation. The object of this scheme is the promotion of international public health by enabling the medical officers of the various civilised countries of the world to familiarise themselves with the health methods which are pursued in countries other than their own. In Great Britain there is, generally speaking, a woeful lack of knowledge of the methods of health administration obtaining in other countries.

The present visit is the second tour arranged by the League's Health Organisation, the first having included Belgium and Italy. It has been organised at the request of the Ministry of Health by the Society of Medical Officers of Health, the details having been arranged by a committee of the Society presided over by Dr. W. J. Howarth, medical officer of health, City of London. The week's proceedings included inspections of the work of the various departments of the Ministry of Health, the Royal Army Medical College, the General Register Office at Somerset House, the institutions of the Metropolitan Asylums Board, the works and laboratories of the Metropolitan Water Board, and the London County Council's housing schemes at Tabard-street and Roehampton. On the social side, also, the week was well filled. The delegates were officially received at the Ministry of Health by Lord Onslow, Capt. W. E. Elliot, M.P., and the chief medical officer (Sir George Newman), and there were receptions at the Royal Sanitary Institute, the Royal Army Medical Corps mess, and the League of Nations Union. The delegates also attended the Pasteur celebration at the Royal Society of Medicine. At the reception on Feb. 28th by the League of Nations Union at 15, Grosvenor-crescent, London, Lord Robert Cecil, chairman of the Executive Committee of the Union, extended a hearty welcome to the delegates, and referred to the circumstance that it was through the generosity of a citizen of the United States, a country still outside the League of Nations, that the visit was rendered possible. Lady Isabel Margesson, chairman of the Hospitality Committee of the Union, also welcomed the delegates.

The investigations in the provinces on which the delegates are now engaged embrace visits to Glasgow and Lanarkshire, Birmingham and Warwickshire, Liverpool and Lancashire, Manchester and Cheshire, the towns of the West Riding of Yorkshire, and Newcastle and Durham County; and the conclusion of the tour will include inspection of the food control work and the port sanitary work in London. The countries represented include the following: Austria, Belgium, Czecho-Slovakia, Denmark, Finland, France, Hungary, Italy, Japan, Jugo-Slavia, Norway, Poland, Roumania, Sweden, Russia, and the United States of America, the last two being still without the League. Future tours of similar parties, including British delegates, are being arranged in other countries, the next being in Austria.

ALCOHOL AND AGE LIMITATION.

THE Teachers' Bill, amending the law relating to the sale of intoxicating liquor to persons between 14 and 18 years of age, will be taken to-day, Friday, March 9th. The Teachers' Committee, which has promoted the Bill, represents a remarkable unity of opinion on the subject. Representatives of great public schools, Catholic as well as Protestant, of grammar schools and of secondary schools, have combined with officers of the National Union of Teachers to bring before Parliament their considered view that the adolescent should be safeguarded from the temptations of alcohol. The main argument employed, in the many public deliveries from responsible persons which have recently appeared, is that, while the present Education Act can claim the adolescent period of boys and girls for education, handing over to the teachers complete supervision of their charges during those impressionable years, the responsibilities of the teachers can only be discharged if they are not thwarted by the countervailing influences which are particularly associated with freedom to obtain alcohol. It is a weighty argument and a well-supported one.

In expressing the opinion that the Bill ought to receive the approval of the House of Commons we are quite aware of the difficulties associated with the fixing of a definite age limit where varying temperaments and conditions are concerned. But restrictions to the use of intoxicants in the case of young persons do not form an interference with national liberty, for the young are dependent upon their seniors and complete freedom of judgment is not their inalienable right. Now recent experience indicates that the age of adolescents is a particularly unstable one, and this fact in all probability accounts for the support of the Teachers' Bill which has been forthcoming from medical men who have had experience in dealing with the evils of alcoholism. Undoubtedly the taste for alcohol often declares itself during adolescence—this we can allow without endorsing the oft-repeated statement that abstinence from alcohol up to 21 will remove apprehension for the future—and we see sound sense in making it difficult for young persons to gratify that taste. The Bill should receive assistance in debate from some of the medical Members of Parliament.

TREATMENT BY RADIUM.

THE history of the development of that modern technique in radio-therapy which is outlined in the report for 1922 of the London Radium Institute (see p. 503) is instructive. Originally the French radio-therapists used only superficial applications of radium. With them grew up ideas on the subject of the employment of different varieties of screening, together with the method of diminishing the destructive action on the skin by cutting off direct irritating and secondary radiation. The burying of screened tubes in growths was the next step in progress, and by this means many tumours could be made to disappear which could not be adequately treated by superficial applications. Subsequently, acting along two different lines of thought, attempts were made in the first place to use only the more penetrating rays by means of very heavy screening, together with the employment of very large quantities of radium, and to use distance by removing the applicator away from the skin surface. At the same time the tremendous amount of energy present in the Beta rays was recognised. They had been employed in the treatment of rodent ulcers and superficial skin lesions, but the American recognition of the possibility of burying small, unscreened glass tubes in tumours made possible the deep use of Beta rays, with considerable improvement in the treatment of hitherto intractable conditions, such as carcinoma of the mouth, although these rays are not applicable in all cases. Later on the surgeon began to recognise the great value of radium in association with surgical procedures in the treatment of malignant disease. Not only can it be used for prophylactic purposes after operation, but the burying of radium tubes at the time of operation may make a case previously regarded as inoperable come within the bounds of the operable. It is difficult by the use of radium alone to make an inoperable case operable owing to the amount of fibrosis which often follows radium treatment, but it is by no means impossible, and the proper use of radium in association with surgery is now mainly a matter of the consideration of the half-dozen different methods of association of the two treatments which are to be combined. The pathologist has by the examination of tumours definitely established the fact that radium can destroy malignant growths, but difficulties arising from situation, from the possible formation of secondary deposits, and from the necessity of avoiding damage to healthy tissues still remain to be solved. Radium has, however, made for itself a definite place in the modern therapy of cancer.

---

[2] Étude de l'évolution des adénopathies hilaires tuberculeuses par la Comparaison des Examens cliniques et radiologiques, Paris, 1922, Jouve et Cie., pp. 60.

Radium has also had an indirect influence in the treatment of malignant disease. The value of a very penetrating ray, susceptible of accurate measurement, in the treatment of deep tumours, was largely the cause of the establishment of the new technique for deep X ray treatment. It led to an attempt being made to produce a penetrating X ray in large quantities and X ray tubes of a regular output. At the present time deep X ray treatment is still a somewhat complicated process involving much mathematical calculation, but doubtless in the course of time it will be greatly simplified. Much work is being done upon the lines of combining X ray and radium treatment, and it is probable that in the future there will be no artificial separation of radium from X rays. The present divorce of these two methods of treatment results mainly from economic causes.

THE Council of the Royal Society recently recommended 15 persons for election into the Society, of whom the following are distinguished in medicine or allied subjects: Dr. E. D. Adrian, university lecturer in physiology, Cambridge; Dr. E. Fawcett, professor of anatomy, University of Bristol; Dr. R. T. Leiper, professor of helminthology, University of London, and director of the department of helminthology in the London School of Tropical Medicine; Dr. J. J. R. Macleod, professor of physiology in the University of Toronto; Dr. F. Horton, Sc.D., D.Sc., professor of physics, University of London (Royal Holloway College); Dr. J. W. McBain, Ph.D., professor of physical chemistry, University of Bristol; Dr. G. A. K. Marshall, director of the Imperial Museum of Entomology; Dr. H. R. Procter, D.Sc., emeritus professor of applied chemistry, University of Leeds; and Dr. W. Wilson, D.Sc., Ph.D., professor of physics, University of London (Bedford College). Amongst the other names is that of Sir Douglas Mawson, D.Sc., leader of the Australasian Antarctic Expedition 1911–1914.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

X.

THE TREATMENT OF EPILEPSY.

IT is not possible in the present state of our knowledge to give a satisfactory definition of epilepsy; it can, perhaps, be best defined as a condition characterised by periodic or irregularly recurring attacks of loss of consciousness, with or without convulsive seizures, the typical attacks being occasionally replaced by other manifestations of a nervous or psychical nature, and though often associated with organic disease of the brain is not itself dependent on any recognisable specific structural changes in it. Epilepsies not associated with demonstrable disease are generally termed *idiopathic*, and it is with the treatment of these I deal here. As our definition of epilepsy is symptomatic rather than pathogenic, our treatment of it can be only symptomatic too. But this does not mean that our aim is only to check the occurrence of seizures, for experience has shown that if we can for a sufficient time arrest manifestations of the disease, or "break the habit of fits," these may not recur when treatment is stopped.

Epilepsy is not a condition that can be treated by mechanical or rule-of-thumb methods, since some epileptics react favourably to one drug only, some to another, and it is usually only by experiment that the treatment most suitable to any case can be determined.

Drug Treatment.

Countless drugs of natural or synthetic origin have been employed, but those which have stood the test of experience are few. Among these bromide, by universal consent, stands first.

Bromides.—The salt employed is a matter of little or no consequence, and a mixture of two or more bases has no advantage. The dose should be that from which the maximum benefit is obtained, provided it produces no unfavourable effects on the patient: rarely more than 40 to 60 gr. a day is required. The depressing or dulling effect frequently attributed to bromide is rarely serious, provided it is carefully administered. It is always preferable to give as few doses a day as possible; frequently two doses, and occasionally one, suffice. Not only is the efficiency of large doses greater, but there is more probability that it will be taken regularly, and absolutely regular and systematic medication is one of the essential elements of success. In cases where the seizures tend to occur about the same hour each day it is important that the drug should exert its maximum effect when the attacks are expected. A dose of 20–30 gr. at bed-time, for instance, frequently checks nocturnal epilepsy. When attacks occur chiefly in the early morning, one dose at bed-time and another of 10–15 gr. immediately on waking, and at least 20 minutes before the patient leaves bed, is advisable. Similarly, when, as is often the case, attacks are more frequent in women at or about the menstrual periods, the daily dose should be increased or even doubled for some days before and during the menses.

Regular and continuous administration is essential; when the most effective daily dose is determined it should not be varied until the patient has been for a long period, at least 18–24 months, free from symptoms. Many failures and even disastrous consequences result from the sudden cessation or diminution of the dose. If greater frequency of the attacks necessitates an increase the later decrease should be gradual, not abrupt. The salt-free diet originally introduced by Richet and Toulouse with the aim of partly replacing the chlorides of the body by bromides, is now less fashionable than formerly, but it is often a useful expedient. When the patient is not under constant supervision the efficacy of the dietary régime may be controlled by estimating the daily output of sodium chloride in the urine.

There are undoubtedly a small number of cases in which bromides are not merely inefficacious but actually harmful, upsetting the physical and mental state of the patient without controlling the seizures; this is most common in minor epilepsy, but it is occasionally so in the major disease too. In such cases other remedies must be employed.

Borates are generally given as sodium biborate, or borax, in doses of 10–15 gr. twice or three times a day, usually in combination with bromides. Borates are undoubtedly valuable drugs in many cases, particularly, in my experience, in major nocturnal epilepsy; but they often check petit mal too, and as the drug has no untoward effects it may be continued indefinitely. In some cases it is as effective as bromide, and may consequently replace it when the latter is not tolerated. Pierre Marie and his colleagues have recently recommended tartarus boraxatus, or sodii boro-tartras, of which as much as 150 gr. a day may be given; it seems doubtful if it possesses any advantages over the simpler preparations.

Calcium salts are occasionally useful as adjuvant drugs. In a small proportion of cases calcium lactate in doses of 7–10 gr. combined with bromide undoubtedly helps to check the seizures. I have found it particularly useful in children in whom the epilepsy is due to or associated with congenital or early acquired cerebral lesions.

Zinc oxide has been recommended in minor epilepsy, but in a recent analysis of a large number of cases under my care I discovered one only in which it had apparently had any influence.

Picrotoxin has a very limited application and is, in my experience, seldom of use. It is, however, one of the constituents of Gelineau's dragées, which are occasionally successful when other remedies fail.

In *belladonna* we have one of the most valuable remedies in the British Pharmacopœia. To obtain its full benefit large doses are often necessary, even 10–15 ♏ of the tincture twice or three times a day, if so much is tolerated. Bromide should always be given with it. It benefits both major and minor epilepsy, but its most striking effects are seen in the latter. One girl, subject from childhood to frequent attacks of petit mal which no other drug controlled, has remained free for several years while taking 15 ♏ twice a day, but the attacks always recur when she drops the drug; and a man, aged 40, who since the age of 17 had, every two or three weeks, series of attacks followed by confusion and violence which repeatedly brought him into asylums, remained three years completely free while taking tinct. belladonnæ 12 ♏ twice a day until last summer, when, during my absence, the dose was reduced to half. The toxic symptoms of the drug, the most important of which are paralysis of accommodation, unpleasant dryness of the throat, and mental excitability, must, of course, be avoided.

Luminal.—In 1912 Hauptmann introduced a new remedy of undoubted value—viz., phenylethylmalonylurea, or luminal. Its sodium salt, which is soluble, is sometimes used, but general experience shows that it is not so effective. The dose varies between 1½–5 gr. per day, but as toxic symptoms are not uncommon it is advisable to begin with small amounts and increase the dose, if necessary, when the patient's tolerance is ascertained. I generally give first 1½ gr. each morning or evening, according as the fits occur most frequently by day or night; then 1 gr., and later 1½ or 2 gr. twice a day if necessary. There are few cases in my experience which require larger doses than 4 gr. a day.

It is particularly in idiopathic major epilepsy that luminal is of service; I have been disappointed with its use in the treatment of petit mal, and of seizures due to gunshot injuries and other gross lesions of the brain. It often arrests or diminishes the frequency of the fits when bromide and other drugs fail, but my experience does not confirm the statements of certain German authors, who claim that it may replace all other drugs, for in my hands it has certainly been less effective than bromide. It seems doubtful if it has an actual curative value since the seizures recur, often more frequently, when it is omitted. It may be administered for long periods, but I find that after a time it is often necessary to increase the dose, as it tends to lose its effect. The most common toxic symptoms are drowsiness, vertigo, disturbances of coördination and speech, rashes, and œdema, and occasionally restlessness and excitability. Changes in character after prolonged luminal treatment, which do not clear up when the drug is stopped, have also been recorded. The intolerance to the drug is said to be reduced by a milk and vegetarian diet. Bromide and other remedies may be given at the same time; personally I have found luminal most useful when combined with these. It has already acquired a reputation in diminishing the excitability and restlessness of patients with mental symptoms, and will be probably found of greatest value in the treatment of epileptic psychoses in institutions where its effect can be carefully controlled.

Other Forms of Treatment.

Various hypotheses as to the nature of epilepsy have suggested many other modes of treatment. It is very doubtful if so-called "reflex causes," as intestinal worms, uterine displacements, ovarian diseases, and ocular abnormalities play any part in the pathogenesis of the disease, but as they may, like other conditions that affect the general health, be predisposing factors, they should, when possible, be remedied. The administration of organic extracts, on the supposition that epilepsy is due to disturbances of endocrine functions, has proved unsuccessful. Partial removal of the adrenals, advocated by Fischer, has been extensively tried in Germany with disappointing and occasionally disastrous results. Protein therapy, which has been recently reintroduced on the assumption that the seizures are anaphylactic phenomena, has apparently yielded favourable results only in the hands of the enthusiastic discoverers of each new method.

General Treatment.

The general care of the patient and the regulation of his life are extremely important factors in the treatment of epilepsy. The measures taken must depend largely on the frequency of the seizures and the physical and mental state of the patient. Provided his general health is fair and that no serious degree of mental deterioration exists, the fewer restrictions placed on the patient the better. Whilst unavoidable dangers should not be run, and occupations attended with risk to themselves and others forbidden, epileptics certainly do much better when they are allowed to lead an ordinary healthy life, and mix in games and work on equal terms with their fellows. Unless the attacks are frequent and severe little or no change in the scope of education is necessary. Plenty of outdoor exercise by day, and long hours of rest at night are advisable. The general rule should be, in fact, to make youthful patients at least feel as little as possible that they are abnormal or different from others.

Diet should be simple, and overloading of the stomach and constipation should be avoided. In certain cases a meat-free diet undoubtedly benefits the patients, but, in my experience, very few cases gain much improvement by the exclusion of meat, though the amount taken can be often usefully reduced. Alcohol in every form should be rigidly excluded.

Special Articles.

THE LONDON RADIUM INSTITUTE.

REPORT FOR 1922.

THIS annual report follows its customary lines. The first and greater portion, written by Mr. Hayward Pinch, gives an outline of the methods used by the Institute in treating diseases of the alimentary canal and its accessory glands. It is obviously intended mainly for the instruction of those not closely in touch with radium work. As a result it is quite conservative in its outlook, and keeps closely to the older and more tried methods of treatment.

The following abstracts of some of the sections give an indication of the broad scope of the report, dealing as they do with diseases of varied pathology affecting different parts of the body.

Fordyce's Disease of the Lips.—Many patients affected with this condition are little troubled by it. In cases where stiffness and soreness, accompanied by a scanty, sticky, mucoid secretion, occasions the patient discomfort, careful examination usually reveals groups of closely aggregated minute white or yellow milium bodies in the mucosa. Exposures of from 20 to 30 minutes' duration with "half-strength" applicators, screened with 0·01 mm. of aluminium, usually suffice to effect a cure, and the condition but rarely recurs.

Epithelioma of the Lip.—Radium therapy should be confined to the treatment of inoperable cases of epithelioma of lip, or of cases in which operation has been refused. It should be carried out both by the burying of several small platinum screened tubes in the substance of the growth, and external irradiation of its surface and periphery. The dose should be a heavy one. All efferent lymphatics and associated lymphatic glands must at the same time receive a prolonged radiation with heavily screened apparatus emitting a gamma radiation. Great benefit is very often obtained in inoperable cases. In instances where operation has been declined, and the growth is relatively small and circumscribed, "apparent cure" of the condition quite frequently results from judicious radium treatment, but this possibility should not be allowed to influence the general rule that operable cases should be excised promptly and freely when consent is given.

Leukoplakia of the Cheeks.—There are three definite degrees of the condition: (1) The affected area is slightly congested, and the epithelium swollen, forming a translucent glistening patch. (2) The patch becomes thickened, opaque, and pearly white in colour, sometimes forming a distinct raised plaque with overhanging edges. In the third stage the patch becomes still thicker, cracked, and fissured, and at the bottom of the fissure ulceration occurs, and may prove the starting-point of an epithelioma. The treatment of these patches with radium varies according to the stage of the disease. In cases of the first degree, exposures of 15 to 30 minutes' duration, with "half-strength" applicators, screened with 0·01 mm. of aluminium, will usually induce the speedy disappearance of the lesion. In the second stage, "half-strength" applicators, screened with 0·1 mm. of lead, should be used, and an exposure of one hour's duration given on two or three successive days. The series of exposures may have to be repeated at intervals of four weeks, until the condition of the mucosa becomes normal or apparently so. These cases show a strong tendency to recur. Third stage must be regarded as definitely precancerous, and the patch should be speedily excised.

Chronic Superficial Glossitis.—This condition may be either hypertrophic or atrophic; the former variety only is amenable to radium therapy. It is characterised by the presence of one or more irregular opaque or pearly white patches on the surface of the tongue, which vary greatly in thickness, and sometimes form raised horny plaques with overhanging edges. The condition is recognised as definitely precancerous. In the early stages great improvement is often effected by exposures of one hour's duration with "half-strength" applicators screened with 0·1 mm. lead, two such exposures being given on successive days. The treatment is followed by a gradual exfoliation of the patch, complete in about four weeks. Recurrence is frequent. In advanced cases radium should not be employed—a local excision is imperative.

Carcinoma of the Tongue.—Some diversity of opinion exists as to the best method in which the actual radium treatment of the tongue tissues should be administered. Some workers embed in the affected area, tiny unscreened glass capsules each containing about 1 millicurie of radium emanation, and allow them to become surrounded by fibrous tissue, or to work their way out at some future date. Others use steel or platinum needles containing 2 or 3 mg. of radium bromide, and embed 10 to 30 of these in and around the growth. They withdraw these tubes after a period of from one to seven days. The practice adopted at the Radium Institute is to use tubes containing 10 mg. of radium bromide, screened with platinum 0·3 mm. in thickness. Any number from 2 to 12, according to the size of the growth, is embedded in and around the lesion, and allowed to remain for six hours, the treatment being repeated after six weeks. The amount of local inflammation that follows upon this procedure is not great. The growth shrinks fairly rapidly, and a considerable fibrosis develops four or five weeks later. The portions which have not undergone satisfactory fibrosis are then treated. General irradiation of the lymphatic area of the neck is carried out.

Chronic Hypertrophy of the Tonsils.—When operation is negatived for any reason, radium treatment will often produce a great improvement in the condition. The process is devoid of discomfort, pain, or danger. Prolonged radiation (24 to 30 hours) with "half-strength" applicators, screened with 2 mm. of lead, should be employed, the apparatus being placed externally immediately behind the angle of each jaw, so as to produce a "cross-fire" irradiation. The treatment may be repeated at intervals of six weeks.

Epithelioma and Sarcoma of the Tonsil.—Operative measures should be resorted to whenever practicable, the whole operation area subsequently receiving prophylactic treatment with powerful apparatus screened with 2 mm. of lead. Any inoperable cases should be treated by the actual burying of a tube of 50 to 100 mg., screened with 1 mm. of silver, in the substance of the tonsil for 24 hours supplemented by a powerful "cross-fire" radiation with screened applicators applied externally at the angles of the jaw. In some cases remarkable improvement results.

Sarcoma.—Sarcoma of the tonsil is much rarer than epithelioma. When too far advanced for excision, radium treatment should be carried out by means of tubes screened with 1 mm. of silver, buried in the substance of the growth, and "cross-fire" radiation from screened apparatus applied externally. The immediate result of the treatment is usually satisfactory, and in a few cases treated at the Institute "apparent cure" has been obtained.

There follow examples of less satisfactory diseases from the point of view of radium treatment, and these are useful as a warning that not too much is to be expected in these conditions.

Carcinoma of the Œsophagus.—This usually originates at one of three sites: 1. At the upper orifice. The post-cricoid growth, 15 per cent. 2. Opposite the bifurcation of the trachea, 32 per cent. 3. At the cardiac orifice, 53 per cent.

1. Post-cricoid lesions tend to affect one portion of the œsophageal orifice rather than completely to encircle it, and the growth is often exuberant and vascular; these facts, and the more accessible position of the growth, enable it to be treated rather more easily than the lower ones. The best method of treatment is to introduce a small pointed tube about the size of a wax vesta, the thickness of the wall of which is 1 mm. of silver, and the strength of the contained emanation equivalent to that of from 70 to 100 mg. of radium bromide. A silken thread is attached to the eyeletted stopper which closes the blunt end of the tube. Direct œsophagoscopy should be performed, and the tube inserted actually within the centre of the malignant growth and left for from 18 to 24 hours. The œsophagoscope should be withdrawn, and the silken thread fastened to the cheek with a strapping. The patient should be kept under hospital conditions for a week or ten days. If the reaction be at all severe considerable œdema may result, leading to great stridor and dyspnœa, possibly calling for tracheotomy. The final result is, however, usually beneficial. It is advisable to subject both cervical regions to a powerful screened "cross-fire" irradiation some two or three weeks after the actual growth has been treated.

2. Carcinoma opposite the bifurcation of the trachea is usually annular and ulcerates rapidly. For such a growth a silver tube with walls of 1 mm. in thickness, and charged with radium bromide or radium emanation of about 100 mg. activity, is mounted at the end of a pliable rubber-covered silver wire, and under direct œsophagoscopy is carefully guided into the lumen of the stricture; the œsophagoscope being withdrawn, the pliable rubber-covered silver wire is moulded to the arch of the palate, and the free end brought out at the angle of the mouth and fastened to the cheek with strapping. The exposure should vary from 15 to 20 hours' duration. Immediate improvement in swallowing follows, due entirely to the mechanical dilation of the stricture by the tube. A few days later congestion causes swelling of the stricture, and renders the dysphagia more acute. When the

congestion passes off a certain amount of fibrosis follows, permanently increasing the size of the lumen. In favourable cases the patient can then swallow food for 6 to 12 months, or even longer, though sooner or later the exposure will have to be repeated.

3. Carcinoma of the cardiac orifice quickly implicates the adjacent portion of the stomach mucosa. These cases are the most unfavourable of all to treat. The result, whatever method be adopted, is not encouraging and little more than some slight transient relief can be hoped for.

Carcinoma of the Stomach.—There are three ways in which such treatment may be given: 1. If the disease be fairly localised and accessible the abdomen should be opened, and one or more radium tubes screened with 1 mm. of silver should be buried at equal intervals throughout the mass for 24 hours, when the tubes are withdrawn and the wound closed. A few encouraging results have been recorded from this method of treatment, but since it calls for a laparotomy it is not devoid of danger in anæmic or emaciated subjects. 2. Radiation of the stomach from the interior. In this method an emanation tube of from 100 to 200 mg. activity is prepared and enclosed in a silver capsule about 2 cm. in length, its wall being 1 mm. in thickness. This capsule is attached by means of a screw stopper to about 3 feet of silken thread. It is then introduced by the finger into the upper part of the œsophagus and swallowed by the patient, its passage being expedited by the ingestion of thick porridge or gruel. The progress of the tube should be noted by means of an X ray screen until it has reached the stomach, and its position should then be charted; the tube remains in the stomach for from 24 to 36 hours, its site being changed from time to time if necessary by traction on the silken thread and then withdrawn. This procedure is effective when there is much ulceration of the stomach mucosa in arresting the hæmorrhage. 3. Radiation with numerous powerful heavily screened applicators. This palliative procedure should be adopted in those cases where methods (1) or (2) are either inadvisable or impracticable. It will often relieve the epigastric pain and arrest the rate of growth and retard the development of ascitic fluid; but this is the utmost that can be expected.

Carcinoma of the Rectum.—This disease is seen in men and women in the proportion of 3 to 1. The greater number of cases are quite inoperable when first examined. When a major abdomino-perineal operation appears in any way practicable it is most strongly urged, as the results far exceed anything that can be expected of radium therapy. Colostomy should be advised in every instance. The constant passage of fæces over a carcinomatous growth invariably stimulates its activity. Experiments have shown that columnar-celled lesions of hypoblastic type were more susceptible to a dosage of a large quantity of radium administered over a short period of time than to a small quantity of radium used for a longer period. For this reason it is advisable to use a powerful radium tube when treating rectal carcinoma, and in cases of the annular type a tube of 200–250 mg. activity, screened with 2 mm. of lead, may be used for a period of 10 to 15 hours. The insertion of the tube is best carried out through a proctoscope, the screened radium being attached to a pliable rubber-covered silver wire about a foot long which is bent at the anal orifice, brought into the fold between the buttocks, and maintained in this position with strapping and a "T" bandage. In the "signet-ring" form of growth the action of the main tube may be advantageously supplemented by the use of smaller tubes containing from 10 to 20 mg. of radium, screened with 0·3 mm. of platinum, and inserted into various parts of the main mass. Many patients are averse to the performance of a colostomy; by the employment of this technique it is often possible to prolong their lives in comparative comfort for four to six years.

The Liver.—There are but few affections of the liver in which radium therapy is likely to prove of any real value. Cirrhosis of the liver, amyloid liver, and fatty liver lie within the physician's province, while tropical abscess and hydatid cysts must be treated by surgical measures. Malignant growths of the liver rapidly prove fatal, palliative treatment only being possible.

Diseases of the salivary glands are also dealt with, the surgical point of view being the one chiefly taken in the consideration of their treatment.

Dr. J. C. Mottram's contribution to the report consists of short summaries of papers written during the year, and is very interesting in that it indicates relationships between radiation, vitamin A and B deficiency, and the known blood changes. It also suggests that a diet rich in vitamins A and B should be given to patients undergoing treatment by radiation.

The physical section, written by Mr. W. L. S. Alter, gives a description of an apparatus devised by him for making emanation tubes without the use of liquid air. For details of the apparatus reference must be made to the report, but it has an advantage over Duane's apparatus devised for the same purpose, inasmuch as it appears less complicated and much less tedious to work.

MEDICINE AND THE LAW.

STOPES *v.* SUTHERLAND AND OTHERS.

IN an action for libel Marie Charlotte Stopes, a Doctor of Philosophy (Munich), President of the Society for Constructive Birth Control and Racial Progress, sued Dr. Halliday G. Sutherland with regard to passages in a book entitled "Birth Control," the publishers, Messrs. Harding and More, Ltd., being also made defendants. In the statements complained of under the heading Exposing the Poor to Experiment, were references to "a birth-control clinic where working women are instructed in the method of contraception described by Professor McIlroy as the most harmful method of which I have had experience," and also a statement that Charles Bradlaugh was condemned to gaol for a less serious crime than the plaintiff's "monstrous campaign of birth-control." The hearing before the Lord Chief Justice and a special jury has ended in a judgment for the defendants upon certain answers of the jury to questions left to them, and as it is stated that an appeal will follow, a statement of the points of law involved will suffice.

The jury found as follows: (1) Were the words complained of defamatory of the plaintiff?—Yes. (2) Were they true in substance and in fact?—Yes. (3) Were they fair comment?—No. (4) Damages (if any)?—£100. Sir Hugh Fraser claimed judgment upon answers (1) and (3), contending that the alleged libels stated above were expressions of opinion and comment which the jury had found not to be "fair comment." Lord Hewart ruled that they were not so, but were statements of fact. Mr. Ernest Charles, K.C., for Dr. Sutherland, argued that on the answers to the first two questions the defendants were at law entitled to judgment; that is to say, that the finding of the jury that the words were true in substance and in fact concluded the matter. The Lord Chief Justice accepted this view in his judgment, in the course of which he observed that he had felt doubt as to whether he should withdraw the question of fair comment altogether from the jury. He said that nobody denied the sincerity, ability, or honesty of purpose of the plaintiff. On the findings of the jury there was no course open to him but to give judgment for the defendants.

It will be seen from the above that if upon appeal it should be held that Lord Hewart was wrong in holding expressions used by the defendant to be matters of fact and not of comment, very considerable argument may take place as to how far answer (3) should benefit the plaintiff in the face of answer (2). It is, we believe, accepted law that a person shall be liable for words found to be defamatory and not "fair comment" upon established facts. Equally there is good authority for holding that a finding that an alleged libel is "true in substance and in fact" is a conclusive answer to an action. There is, in short, an element of contradiction and uncertainty, the removal of which by the Court of Appeal or a higher tribunal may benefit future litigants, however costly and inconvenient the process may prove to those now involved.

CHILDREN BORN OUT OF WEDLOCK.

The principle involved in the Legitimacy Bill now under consideration in the House of Commons must receive universal approval. Its object is to legitimise illegitimate children whose parents marry either before or after the passing of the Act, and it was supported by members of each party. The Bill has been ably drafted by Mr. H. B. Betterton who introduced it, and although certain amendments may be made during the

Committee stages it is being sympathetically considered by the Government. Some of those Members of Parliament who have in recent years been responsible for the introduction of more comprehensive measures are inclined to consider it unduly narrow, since no provision is included for the more material side of the child's welfare. Another private measure which supplements the Legitimacy Bill in this respect is the Bastardy Bill, sponsored by Captain Bowyer, which provides for increase in the amount payable under an affiliation order, and the universal appointment of collecting officers. If these Bills run concurrently through both Houses at least some of the injustices under which the illegitimate child now suffers may be removed.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

District Health Scheme in Madras Presidency.

THE Madras Government has just issued an order reviewing a report of the district health officer, Vizagapatam, in connexion with the investigation of cholera in that district. The report was the first received by Government of the operations of the new district health staffs appointed in the districts, and therefore was considered worth publishing. The Government, in issuing orders based on the report, observed that the arrangements made for the distribution of water and medicine to the houses of those infected were admirable, and enabled the protective staff to localise and insulate the epidemic. The efforts of the health staff were reinforced in exemplary fashion by the presidents of the taluk boards and union boards affected, and by the active coöperation of the people themselves, notably volunteers who distributed medicines from house to house in the infected areas. These kept the staff in closest touch with the progress of the epidemic, enabling the district health officer to concentrate his staff exactly in the areas where it was most needed. The staff propaganda was enthusiastically seconded by presidents and members of local boards involved, and was appreciated by the villagers. The need for and utility of practical instruction in hygiene was fully vindicated. The district health officer drew a lurid picture of the squalor in which the labouring class of Parvatipur, among whom the epidemic first took root, live. Unless some permanent improvement in their environment can be effected these quarters will continue a menace to the health of the whole countryside. It is understood that the experimental scheme for district health staffs has worked successfully, and that the complete scheme will be introduced from April 1st, 1923.

Infant Mortality in India.

Bombay has recorded the highest mortality among infants under one year. Whereas in London, in 1921, the ratio of deaths of infants under one year was 80 per 1000, in Bombay the ratio was 666 per 1000 births. Figures contained in the annual report of the Director of Public Health of the United Provinces further emphasise the need for measures that will lead to the lessening of the toll that death takes of infant life. The statistics show that last year there was an increase in the already appalling infant mortality rate. In the district the average rate was 236·53 compared with 220·25 in the preceding year; in the municipal area the rate was 321·04 as against 303·24; while in 47 notified areas the rate was 283·84 as against 248·98. The rate in the urban areas was 314·27 and in the rural tracts 229·93, as compared with 300·02 and 213·83 respectively in 1920.

The Drug Habit in India.

An illicit traffic in the importation of morphia is flourishing at Indian ports. Already the Customs have seized 96 ounces of this drug, which, on being landed, commands a wholesale price of Rs.15 per ounce. The demand for morphia, especially in up-country places, is said to be increasing, and the retail price in the United Provinces and the Punjab is as much as Rs.80 an ounce. In the last five months 475 ounces of cocaine have fallen into the hands of the Customs preventive officers, as compared with 263 ounces in the whole of 1921–22.

Hospital Overlapping in Madras.

The Surgeon-General with the Government of Madras urges the need for a concentrated effort to coördinate medical activity in the Madras Presidency and recommends that a complete survey should be made of the hospitals and dispensaries in each district and their work reorganised in such a manner as to prevent overlapping. He pointed out that at present medical institutions were scattered about without any definite plan, with the result that in some towns there were hospitals owned by local boards and missionary bodies which kept up a perpetual rivalry. In one district there were 11 dispensaries, in one of which only 20 persons were treated for minor ailments. As some dispensaries do not provide sufficient work for the medical officers in charge, efforts are in future to be made to send medical relief from such dispensaries to surrounding areas and villages by closing them on certain days in the week and sending the medical officers on itinerant duty.

Insanitary Towns in the United Provinces.

At a recent meeting at Lucknow of the Board of Public Health in the United Provinces, several inspection reports by officers of the Public Health Department on the sanitary condition of towns in the Provinces were placed before the Board with notes of the action proposed to be taken by the municipal board concerned. In nearly every case the Board considered the action was inadequate and the reports on the Agra Municipality were forwarded to the Government with the remark that the Board of Public Health considered the inaction of the Agra Municipal Board unsatisfactory.

Medical Units of Auxiliary Force.

Steps have been taken to organise at Bombay and Madras medical units of the Auxiliary Force, including motor-ambulance convoy companies.

Madras, Feb. 1st.

CZECHO-SLOVAKIA.

(FROM OUR OWN CORRESPONDENT.)

National Tuberculosis Congress.

A NATIONAL congress for research in tuberculosis will be held in Prague from May 19th to 21st. Organised by the Czech Association for the Promotion of Research in Tuberculosis, of which Prof. Ivan Honl is chairman. The congress will comprise three sections. The first section will consider theoretical and clinical questions, the second will be devoted to public health, and the third will deal with tuberculosis in veterinary medicine. At the same time an exhibition will be held at which all Czecho-Slovak anti-tuberculosis organisations will demonstrate their activities. Papers will be read by tuberculosis workers who hold scholarships given by the Czech Association. Foreign associations have not been officially invited to the congress, but foreign guests will be made welcome, in accordance with a resolution passed by the organising committee. Intention to attend should be communicated to the Secretariat of the Congress, Vladislavova 14, Prague.

National Council of Social Hygiene.

The National Council of Social Hygiene, a federation of nine private associations dealing with public health, held the sixth session of the delegates on Feb. 7th. At the meeting Dr. Alice G. Masaryk, daughter of the President of the Republic, was re-elected chairman of the Council. Prof. Selskar M. Gunn, of the Rockefeller Foundation, who formerly held the post of technical advisor to the Ministry of Health at Prague, stated in an address that the creation of the Council led to the organisation of a similar institution in

Belgium and Finland, and that the League of Red Cross Societies included in its programme the initiation of similar councils in other countries. A report was presented relating to the common effort to raise funds which will be undertaken by the constituent associations during the spring. A building to include the offices of all these associations is projected; the financial side is provided for, and only technical elaboration is now required before the scheme is carried forward. A committee was appointed to take charge of a scheme propounded and carried by the Czecho-Slovak Red Cross, whereby a coöperative demonstration of model social and public health work will be undertaken by the constituent associations of the Council in the district of Kladno; there the different associations will work out their respective relationship in the details of field work, and all classes of public health personnel will be trained in practical field experience. The district has a population of 81,034 inhabitants according to the census of 1921, and contains two industrial towns with a combined population of 29,476; the rest of the district is rural, and it was selected for the experiment because of these mixed features. The Ministries of Public Health and Social Welfare have been invited to participate in the undertaking. A smaller demonstration of local work will be conducted simultaneously by the Czecho-Slovak Red Cross in the community of Lány, where is the summer residence of the President of the Republic.

The Wet-Nurse as a Mother.

A Bill was recently introduced in Parliament by Deputy Dr. Ivan Hálek to restrict the employment of any wet-nurse to the detriment of the latter's own child. A common practice has been that a poor mother accepted the position of a wet-nurse in a rich family, while her own child was entrusted to the care of relatives—a proceeding which naturally entailed artificial feeding of the child. The proposed Bill would permit the hiring of a wet-nurse only on condition that her own child is nursed by her simultaneously with the child of her employers. Wet-nurses willing to nurse for hire are usually of strong physique and have milk enough for two children; moreover, it is anticipated that a mother who does not want to nurse a child because she can hire a wet-nurse may not care to take into her home a nurse with a child of her own, and will therefore prefer to nurse the child herself. Where a mother cannot nurse her child, and does not want to hire a nurse with a child, she will probably feed her own child artificially under conditions more hygienic than those attainable by the relatives of the poor child whose mother has become a wet-nurse. From the eugenic standpoint it is more likely that the child of a strong mother will develop into a healthy individual than the child of a mother unable to nurse it, and the Bill is aimed at restriction of "immoral commerce" in mothers' milk; it is felt that a reduction of infant mortality should result from giving the child of poor parents the benefit of its own mother's milk rather than from helping the weaker offspring of wealthy parents to the detriment of the stronger child.

Plumbo-Solvent Water at Bacup.—An inquiry held in Bacup on Feb. 27th by inspectors of the Ministry of Health revealed the fact that the water supplied by the Bacup Corporation to the Rochdale Corporation contained lead in dangerous quantities. Samples were taken at houses of water which had stood in the pipes all night. Analysis of the water supplied in Bacup itself in almost all cases gave similar results. The reason assigned for the plumbo-solvent action of the water was the presence of peaty acids due to the nature of the collecting areas. It was considered that the only efficient remedy was mechanical filtration of the water at its sources. It is proposed to instal at the reservoirs four Bell's patent mechanical filters, at a cost of £16,000, to remove peat and suspended matter, as well as the plumbo-solvency. It was recalled at the inquiry that in 1887 there was a serious outbreak of lead poisoning at Bacup, when several deaths occurred and 600 cases were treated.

Public Health Services.

The School Medical Service and the Student.

The professor of medicine at the University of Aberdeen is to be congratulated on his enterprise in including in the curriculum for fifth-year medical students certain lectures by the school medical officer, Dr. George Rose, on school medical inspection and treatment with their bearing on medical practice. During the last session visits were paid to special schools and clinics and attendance at the lectures was large and the interest keen. It is to be hoped that the practice will spread so that the medical student will be enabled to take advantage of the vast field of pediatrics open to him in this direction. There are doctors throughout the country who have never seen a school medical inspection, a school treatment centre, or even one of the various types of special schools. As was noted recently in our columns, at Liverpool work at the schools and at dental centres is included in the university dental curriculum.

Quarantine Period for Measles.

The new Board of Health regulations for New York lays down that children and teachers with measles are excluded from school but are permitted to return five days after the appearance of the rash, provided the rash and all catarrhal discharges have disappeared. Those who have not had measles are excluded until 14 days after the date of their last exposure.

PUBLIC HEALTH IN THE CITY OF CAPE TOWN.

We recently reviewed[1] Dr. J. A. Mitchell's survey of public health in the Union of South Africa contained in an address to the recent Johannesburg Congress. Dr. Mitchell then challenged the medical profession to say what it was doing about the matter. We have now received from Dr. Jasper Anderson, the medical officer of health of Cape Town, a copy of his annual health report for the year ending June 30th, 1922. It is an interesting document, giving as it does the vital statistics of a European and non-European community living side by side and enabling a comparison to be made between the health conditions of either community and those of the average English town. Dr. Anderson mentions that the general death-rate and the infant mortality for both communities are the lowest ever recorded and that this result has been achieved in spite of overcrowding and scarcity of house accommodation. The following table gives some of the principal statistics for the Europeans and non-Europeans separately:—

—	Estimated population for mid-year 1921–22	Birth-rate.	Death-rates per 1000 of population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Infant mortality.	Diarrhœa, &c., under 5 years.	Maternal mortality from childbirth.
Europeans	103,520	24·2	11·9	1·0	0·88	1·7	69	13	4·0
Non-Europeans	82,530	51·6	27·5	3·7	0·52	7·6	176	30	3·8

The general death-rates when corrected for visitors become 10·6 and 26·2 respectively. The rates for the European community compare favourably with an English town, especially that for cancer. Among non-Europeans the most noteworthy features are the high birth-rate, the high death-rates from tubercle, respiratory diseases, and among infants, and the low death-rate from cancer. The child-birth mortality is slightly lower for the non-Europeans and much on a level with an English town. As regards diarrhœal diseases, only three deaths from dysentery were recorded, and taking into consideration temperature conditions, the death-rates appear to be comparatively favourable. There may be some difference in classification, but even when diseases of the stomach are added to diarrhœa and enteritis, the death-rates per 1000 births only become 30 and 67 for Europeans and non-Europeans respectively.

---

[1] The Lancet, Jan. 6th, p. 48.

The total hours of bright sunshine were 2801 and are to be compared with a 15 years' average of 2980. The rainfall was 24·15 inches, the 15 years' average being 22·19 inches. The range of the four-foot earth thermometer was from 56·8° to 69·1° F., as compared with an average range for 15 years of 56·8° to 81·4° in the shade. The mean of the maximum thermometer for the year was 70·85° (15 years' average, 70·56), and of the minimum 52·03° (15 years' average, 53·85). The highest shade temperature recorded was 99·3° on April 4th, the highest during the previous 15 years being 102·5° on April 21st, 1918.

Enteric fever was most prevalent from January to May and caused a death-rate of 0·26 per 1000 among Europeans, and of 0·56 among non-Europeans. For the previous year these rates were 0·42 and 0·63 respectively—enormous figures, as Dr. A. W. Reid, the assistant medical officer of health says, compared with present English rates. One could, however, have matched them in some English towns in the last decade of the nineteenth century. The death-rate from diphtheria was high—viz., 0·86 for Europeans and 0·72 for non-Europeans. The maternity and child welfare work was directed by Dr. Mary Van Ingen. There are five bureaus for infant consultations and a staff of 10 sanitary inspectresses, and a chief inspectress. Of 6905 notified births, 5796 were notified by midwives, 1098 by parents, and 11 by doctors. Patients considered suitable have tuberculin treatment at the city hospital and continue the treatment after discharge at the tuberculosis bureau, which is also used for consultation purposes. Dr. W. P. Cooney conducts the municipal V.D. clinic and finds much difficulty in getting the more illiterate patients to take the treatment seriously. Dr. Reid gives a very favourable report of the 108 dairy-farms outside the city, which supply Cape Town with milk. For example, the stables and utensils are clean, the milkers wash their hands before milking, and coolers are in general use.

Progress is being made with the extension of the water-carriage system. Extermination of rats and mosquitoes receives continuous attention. There were no deaths attributed to malaria last year.

Obituary.

PETER CALDWELL SMITH, C.B.E., M.D., C.M. GLASG., D.P.H. CAMB.,

MEDICAL OFFICER OF HEALTH FOR WANDSWORTH.

THE Public Health Service, both civil and military, has sustained a severe loss through the death on Feb. 21st of Dr. P. Caldwell Smith, who had for many years taken a prominent part in London civic life as medical officer of health of the metropolitan borough of Wandsworth, and did valuable work during the war in the medical service of the Territorial Force.
